Nickel.—0.3 gm. of alloy is weighed into a 400 c.c. beaker, 50 c.c. of solution of sodium hydroxide (15%) added, the liquid is boiled, diluted with hot water, allowed to settle, and filtered, rejecting the filtrate. The filter and residue are transferred to the original beaker, and the residue dissolved in nitric acid (sp.gr. 1.18), diluted with a little hot water, and filtered into a 450 c.c. beaker, and the precipitate washed with hot water. To the filtrate a solution of ammonia (sp.gr. 0.90) is added until a very slight permanent precipitate is formed, then 15 c.c. of saturated solution of sulphur dioxide is at once added, the mixture heated to boiling, and a slight excess of decinormal solution of ammonium thiocyanate added. After boiling for ten minutes, with constant stirring, the mixture is allowed to stand for an hour, when the cuprous thiocyanate is filtered off and washed with hot water. The residue and filter paper are rejected. To the filtrate in a 1000 c.c. conical flask, 2 grms. of tartaric acid and 2 c.c. of sulphuric acid (sp.gr. 1.84), are added, a solution of ammonia (sp.gr. 0.90) added until neutral, and sulphuric acid (3%) until faintly acid. A solution of ammonia (sp.gr. 0.90) is now added to exact neutrality and 15 c.c. of 2N ammonia solution added. The liquid is cooled thoroughly and titrated with N/10 solutions of potassium cyanide and silver nitrate, using 2 c.c. of 2% solution of potassium iodide as indicator.

If the copper be estimated first, the amount of N/10 solution of ammonium thiocyanate required to precipitate all the copper and leave a slight excess of the reagent can be easily calculated.

A typical analysis of one of these rich alloys is Cu 30.2%, Fe 1.59%, Ni 16.63%.

DISCUSSION.

Mr. H. DROOP RICHMOND asked, in connection with the first class of alloys containing aluminium and copper, whether any use had been made of the large difference which existed between the density of aluminium and that of copper as the basis of a method for control work. Having had to examine a large number of solders with the object of classifying them, he had found that the specific gravity enabled the percentage of lead and tin to be calculated with an accuracy of about 1%. In the case of solders containing antimony, the method did not apply and it was necessary in such cases to estimate the antimony. If a similar method were employed for the examination of the copper-aluminium alloys, it should be possible to get much greater accuracy than in the examination of solders. Was it desirable in the estimation of aluminium and iron by precipitation of the metals as hydroxides by the addition of ammonia, to neutralise the solution exactly by the employment of an indicator, or was the addition of excess of ammonia and its subsequent removal by boiling equally satisfactory?

Dr. E. B. R. PRIDEAUX asked whether any attempt had been made to devise a rapid test for the examination of these alloys, depending upon their magnetic properties. He did not know whether these alloys possessed magnetic properties, but from the fact that Heusler's alloy, which contained aluminium, copper, and manganese, was distinctly magnetic, he considered it a possibility. He further suggested that the amount of hydrogen evolved on treating the alloy with alkali and then the alkali-insoluble matter with acid might be made to yield a "mean hydrogen equivalent" from which the composition of the alloy could be deduced.

Mr. T. H. ADAMS expressed his disappointment

that a method for the direct determination of aluminium had not been forthcoming. In his opinion the figure obtained by difference was not satisfactory. The most useful method he knew consisted in precipitating the aluminium as phosphate after removing the other metals, but he confessed that owing to the small quantity of the sample on which one had to work on account of the bulky nature of the precipitate, the results were not reliable to within, say, 0.2%. The authors stated that they estimated zinc by precipitation as sulphide from alkaline solution. A much better method was to precipitate in a solution faintly acid with sulphuric acid and containing a little sulphurous acid. The presence of the sulphurous acid caused a co-precipitation of sulphur in such a form that the whole precipitate was almost granular and could be readily filtered and washed with cold water.

Mr. J. M. WILKIE said that he was somewhat astonished that the electrolytic methods had been neglected by the authors on account of the superior rapidity of the chemical ones, and recalled the work of Dr. H. J. S. Sand on the rapid determination of metals by the method of graded potential and rapidly rotating electrodes. With regard to the use of sodium fluoride in the iodometric determination of copper to avoid interference by ferric salts, it was evident that the action could only be accounted for by the non-ionisation of the complex sodium ferric fluoride. This non-ionisation of the soluble fluorides was very interesting from the theoretical standpoint; it was necessary to bear in mind that phosphoric acid possessed a somewhat similar action, so much so that in the iodometric determination of ferric salts a much higher concentration of hydrochloric or sulphuric acid was required in the presence of appreciable amounts of phosphoric acid to produce any coloration. The effect of adding phosphoric acid to the coloured solution of ferric chloride was quite marked, for the solution became colourless. The rapidity of the thiosulphate method for the precipitation of copper sulphide with the elimination of hydrogen sulphide, and the physical condition of the copper precipitate obtained were so marked features that it had always surprised him that the method was not more widely used. That the authors adhered to the stannous chloride-mercuric chloride method for the reduction, and subsequent titration with permanganate for the determination of iron, showed that in their opinion this early volumetric method had not been displaced by more recently devised processes. With regard to the determination of ferrous iron by titration with permanganate in the presence of hydrochloric acid, Jones and Jeffrey some years ago claimed that in the presence of Reinhardt's solution (manganese sulphate, sulphuric acid, and phosphoric acid) accurate results were dependent on the rate of addition of the permanganate to the ferrous iron solution. However, later workers had not entirely confirmed this. The iodometric relations of ferrous and ferric salts possessed peculiar features of interest. The authors, as already mentioned, used sodium fluoride when it was desired to determine copper iodometrically, but it was also possible to determine ferric salts iodometrically in acid solution with considerable accuracy in the presence of very varying concentrations of free acid, and finally ferrous salts could be determined iodometrically in the presence of ferric salts by a very convenient method devised by Romijn. The ferrous material was dissolved in *N/1* hydrochloric acid and sodium pyrophosphate added and then excess of standard iodine. After standing a few minutes the excess was determined by means of standard thiosulphate solution. This method of Romijn was exceedingly useful for the determination of ferric iron in organic materials.

Mr. GRISLEY stated that the estimation of copper in copper pyrites was satisfactorily accomplished by titrating an ammoniacal solution with potassium cyanide, and suggested this method for use in connection with the estimation of the copper present in aluminium alloys.

Mr. COLLITT, in reply, said that they had had no need to use such a mechanical method as the specific gravity determination owing to the rapidity and accuracy with which the iodometric determination of copper could be carried out; it was possible for one operator to perform 30 or more estimations in duplicate during the course of a working day. For a similar reason he had made no attempts along the lines suggested by Dr. Prideaux. For control analysis he did not consider that electrochemical methods for copper and nickel were of any advantage owing to the accuracy and rapidity of the chemical ones, but he added that the one case in which the electrochemical method would probably supersede the chemical one was for the estimation of zinc. He considered that the volumetric estimation of iron employing the stannous chloride method of reduction, was entirely satisfactory, and he stated that it was the standard method in use at the present time in America and Germany for iron ore analysis, and further that probably 75% of the iron ores of the world were valued on the basis of the results obtained by this method.

Meeting held at University College on Wednesday, March 20th, 1918.

DR. R. M. CAVEN IN THE CHAIR.

THE PREPARATION OF "STANDARD" PLANTATION RUBBER: A NEW METHOD OF COAGULATION.

BY M. BARROWCLIFF, F.I.C.

Doubtless owing to conditions imposed by the war, the question of the preparation of a standardised plantation rubber has not, apparently, during the last three years, continued to receive the attention that was formerly being paid to it. That little, if any, real advance has been made towards the solution of the problem is shown by the heavy premium which still persists in favour of Brazilian rubber. At the present time (Feb., 1918), the respective prices of "Fine hard Para" and plantation rubber are 2s. 8d. and 2s. 3d. per lb. When it is remembered that Para rubber shows, on washing and drying, a loss greater by about 12% than does plantation rubber, the premium in its favour is seen to be equivalent to 9d. per lb., or 33%.

The reason for the obvious partiality shown by the manufacturer for Para is that plantation rubber, even of the highest grades, varies in quality, the variations being considerably greater than those found in different samples of fine hard Para. Much experimental work, dealing with the causes of this variability, has been published, notably by B. J. Eaton and J. Grantham. It was found that it is almost solely in respect of the time of heating required to ensure correct vulcanisation, that is, to afford a vulcanised rubber having the best mechanical properties, that the variations occur. Samples of plantation rubber, prepared by the different methods in general use, were found to require for the correct "cure" widely varying times of heating, at a constant temperature. Further, rubber made by the same process, on different estates, and at different times on the same estate, was found also to vary greatly in this respect. When, however, the proper time of heating had been found and applied, relatively

small differences were noted in the mechanical properties possessed by the vulcanised samples.*

The fundamental fact established by Eaton and Grantham is that the time factor for correct vulcanisation varies inversely according to the degree to which the rubber coagulum has been allowed to remain, subsequent to coagulation, unworked, and in contact with its serum. The longer this period the shorter the length of heating required to produce a correct cure.†

Bearing this in mind, also the fact that the present custom is to machine the rubber on the day following coagulation, the influences exerted by the various factors introduced, in practice, into the manufacture of rubber from latex can be accurately foretold. The greater the extent to which the coagulum is machined, and the more completely the serum is consequently washed out, the slower the rate of "cure" of the rubber produced. This "crêpe" rubber, as now marketed, is the slowest to vulcanise. "Sheet"

the latex (the usual method) is to retard markedly the rate of cure, as will be seen from figures given below. Little difference is occasioned, however, between acid-coagulated rubbers, by variations in the amount of acid that has been used, at all events within the limits met with in practice.

As is obvious from the foregoing, to produce a uniform rubber without some radical change in method would involve almost insuperable difficulties. One type of rubber only could be permitted; whilst present-day smoke houses, drying rooms, and much machinery, would have to be "scrapped," in order that the necessary standardised mechanical treatment could be introduced. The way out of this difficulty is clearly indicated by Eaton and Grantham's further work.

It was found that the change which takes place in the rubber coagulum and causes the diminution in the time of heating required for vulcanisation is completed in the course of a few days. This is shown by the following figures* :—

	Optimum time of cure, 2½ hrs.	Breaking load, kilos. per sq. mm. (a).	Elongation of break, (original length = 100) (b).	Product (a × b).
<i>Pressed slab.</i>				
Crêped 1st day after coagulation	2½	114	1012	1153
" 4th day	1½	150	1038	1557
" 7th day	1½—1½	150	976	1464
" 10th day	1½	151	1032	1558
<i>Coagulum.</i>				
Crêped 1st day after coagulation	2½	125	997	1246
" 4th day	2	159	988	1570

" 10th day	1½	138	1001	1381

rubber, which receives a much less drastic machining and retains a considerable quantity of serum, that drains out relatively slowly, cures in a much shorter time, whilst "slab," which receives no mechanical treatment and in which 12% to 15% of moisture is allowed permanently to remain, vulcanises still more quickly.

In the preparation of "smoked" rubber two variables are concerned: (a) the action of the smoke products; (b) the temperature of drying. The former retards the rate of cure, whilst the latter, within the limits attained in practice, accelerates it. Hence "smoked" sheet may cure either faster or slower than similar unsmoked sheet, depending on the balance of these factors in the earlier stages of drying.

In the case of unsmoked rubber the rate of drying similarly affects the vulcanisation time factor. The same plantation drying room may produce, on different days, according to the temperature and atmospheric humidity, rubber having different rates of "cure," even if the moisture content of the wet rubber happened, on each occasion, to be the same.

The amount of serum left in "sheet" rubber depends on the machining it has been given. Eaton found that the more concentrated the latex the more rapid is the rate of cure of the "sheet" afforded by it. The coagulum from the undiluted latex being thicker and harder, more serum is retained in it after the "rolling" process: the rate of drying, consequently, is slower than in the case of the thinner sheet afforded by the diluted latex, affecting, in the way expected, the optimum time required for the "cure."‡ Similarly, "differential" rolls and rolls of equal size and speed will produce sheet rubber requiring differing times of "cure," other factors being constant. The effect of employing acetic acid to coagulate

In each case the latex was diluted to the same degree and coagulated with acetic acid. Although the maximum effect appears to be attained about the 7th day, it is seen that there is little change in the rate of vulcanisation after three days, when the vulcanised rubber possesses the best mechanical properties. The slower progress of the change in the coagulum, as compared with the slab, is probably due to putrefactive changes having occurred. To obtain the best results, therefore, the coagulum should be left unworked for three days. It is then immaterial to what extent the rubber is worked, in what form it is finished, or how quickly or slowly it is dried, the time of "cure" not being affected to any significant extent.

If, however, coagulation is carried out in the usual way with acetic acid in open vessels, the rubber coagulum undergoes changes, if kept such a length of time, which render the method unsuitable. Putrefactive action sets in, accompanied by darkening of the coagulum, whilst spot diseases, which have been shown to cause an extraordinary retardation of "cure," are likely to develop during the subsequent treatment.

A new procedure is required, therefore, and seems to be furnished by the method introduced by M. Maude and W. S. Crosse, known as the M.C.T. process.† It is based on the fact that in closed vessels, latex coagulates completely without the addition of acid and without at the same time undergoing putrefactive changes. As now carried out in practice, large cement tanks provided with heavy water-sealed covers are used. These are filled with the bulked latex, leaving the smallest practicable air space. The covers are affixed and sealed and left undisturbed until the following day, when coagulation is found to be complete. The resulting coagulum is converted into "crêpe" in the usual manner.

Addition may be made to each 100 gallons of

latex of a quantity of a soluble calcium salt, *e.g.*, calcium acetate or sulphate (gypsum), corresponding to 4 oz. of calcium. The effect of this is to accelerate the coagulation. A beneficial effect on the properties of the rubber may also be produced; but evidence on this point is not yet available. In this connection there merits notice the fact that whereas the soils of the Amazon region are well supplied with lime those of the Malay Peninsula are remarkably deficient in this respect. Further,

a pressure of one or two atmospheres, which has the effect of keeping in solution the carbon dioxide of which the bubbles consist. For this purpose it is necessary to use iron pressure vessels provided with partitioned removable aluminium linings.

The following vulcanisation results afforded by rubber prepared by this method are contained in a report by Mr. B. J. Eaton to Mr. Maude, then manager of the Cicely Rubber Estates (April, 1917):—

the Para method of coagulation favours the retention of calcium compounds by the rubber, whilst acid coagulation tends to remove them.

For comparison are given the following standard figures, afforded by good specimens of plantation rubber and fine hard Para.

Source of rubber.	Optimum time of cure.	Breaking load, kilos. per sq. mm. (a).	Elongation at break (original length = 100) (b).	Product (a × b).
<i>Unsmoked sheet.</i>				
<i>Cicely Estate.</i>

" "	1	1.47	973	1437
Diluted latex (1:1)	1½	1.50	962	1443
Ratanui Estate latex	1½	1.45	978	1418
" "	1½	1.39	940	1222

Source of rubber.	Optimum time of cure, hrs.	Breaking load, kilos. per sq. mm. (a).	Elongation at break (original length = 100) (b).	Product (a × b).
Slab	hrs. 1½	1.51	1032	1558
Sheet (unsmoked)	2½	1.52	969	1473
Sheet (smoked)	2½	1.46	973	1420
Thin crêpe	3½	1.30	930	1209
Fine hard Para	2½	1.52	1034	1571

These points may be not without bearing on the causes of such differences as may exist between Para and plantation rubber.

For the manufacture of "sheet" the tanks are suitably partitioned. "Sheet" rubber so made contains usually a number of small bubbles. This can be obviated, if desired, by coagulating under

Regarding these results, Eaton states: "All the samples possess excellent tensile properties, equal to the best samples of plantation sheet and crêpe, and prove that the process is capable of producing rubber of excellent quality." It is to be noted that all the above rubber was manufactured within 24 hours of coagulation. This

accounts for the difference in the rate of cure shown by the three types, slab, sheet, and crêpe.

The uniformity of the samples of crêpe rubber is remarkable, considering that they represent the produce of old and of young trees; of pure latex and latex diluted with water; of rubber made on different days. The rate of cure is seen to be more rapid than in the case of the standard sample of crêpe, a result attributed by Eaton to the absence of acid.

The above figures are given in order to show that this method of coagulation affords, at least, rubber equal in all respects to the best now being produced by acid coagulation, and of greater uniformity. The point upon which stress requires to be laid, however, is that it is a process, and seemingly the only practical one, by which the coagulum may be allowed to mature for the length of time essential for eliminating the differences that otherwise result from unstandardised subsequent treatment.

For the production of "standard" rubber the bulked latex from a day's tapping requires to be placed in the coagulating tanks, as described above, and allowed to remain undisturbed for a fixed time, which, it is suggested, should be three days. Under these conditions no putrefaction occurs and the coagulum remains perfectly white, except for a slight surface darkening.

Judging by the considerations advanced above the rubber so produced, whatever the source, or whether finished as crêpe or sheet, would show no variations in the time of heating required under standard conditions for correct cure, whilst the vulcanised material would possess the maximum attainable tensile strength. The cure would be substantially quicker than that of Para under similar conditions, but this is an advantage as it enables the manufacturer, whilst heating for the same length of time, to vulcanise at a lower temperature, which is all to the benefit of the finished material.

The result of the general adoption of the above described *modus operandi* would be the production of a plantation raw rubber as uniform in its vulcanising properties as fine hard Para, and one affording at least an equally satisfactory vulcanised product.

Sydney Section.

Meeting held on Wednesday, November 21st, 1917.

ON THE RELATION BETWEEN THE DEGREE OF SUPERSATURATION, THE REFRACTIVE INDEX, AND THE TEMPERATURE OF SUGAR SOLUTIONS.

BY E. V. MILLER AND F. P. WORLEY, M.A., D.S.C.

In the industrial operation of crystallising sugar from solution, by evaporation in a vacuum pan, the temperature of evaporation is intentionally varied at different stages of the process; but notwithstanding this variation the solution must of course be kept always in a supersaturated condition, otherwise the process of crystallisation would be stopped or reversed. It would be of assistance to the operator to know at any moment the degree of supersaturation of the solution in which the crystals of sugar were forming or growing. In the absence of any direct method of expeditiously determining the degree of supersaturation, an indirect method has been devised. An instrument, to be described in a subsequent paper, has been constructed by one of us which will at any

time show at a glance the refractive index of the liquid portion of the contents of the vacuum pan. The temperature is easily ascertained. From these data the supersaturation may be inferred, provided certain relations existing between temperature, refractive index, and degree of supersaturation of sugar solutions are known.

Theoretical.

It is necessary to state what is meant by "degree of supersaturation," since this may be defined in a variety of ways. In making a choice among these, regard should be had to the forces operative in inducing crystallisation, and in determining its rate. These are (1) the excess of osmotic pressure over the solution pressure, *i.e.*, its excess over the osmotic pressure of the saturated solution, and (2) the viscous resistance to the movement of the molecules of sugar in the solution. Knowledge of the magnitude of these two forces in a crystallising solution would probably carry the operation of crystallisation completely out of the rule-of-thumb stage in which it exists at present: so that in reality the mere knowledge of the degree of supersaturation existing in a solution is desirable only in so far as it gives some indication of the first mentioned of these forces. In defining, therefore, a scale of supersaturation we should aim at having its degrees as nearly as may be proportional to equal increments of the force which operates in favour of crystallisation. A method of specifying the supersaturation which has considerable vogue is deficient in this important respect. It is a mere numerical co-efficient, having unit value when the supersaturation is zero. It gives no indication of the excess osmotic pressure.

Recent work on the variation of osmotic pressure with concentration, in concentrated solutions, has shown that at constant temperature the pressure varies approximately in proportion to the ratio solute: solvent. In accordance with this law we define s , the degree of supersaturation, as follows:

Starting with a quantity of saturated solution containing 100 grms. of water, imagine s grammes of sugar to be dissolved in it, the initial and final temperatures being the same. Then s will be the degree of supersaturation existing in the solution.

If P is the percentage of sugar in a saturated solution at a given temperature, and S the quantity of sugar per 100 of water in the same solution, the relation between these systems of evaluation is given by

$$P = \frac{100S}{100 + S}$$

from which we find

$$S = \frac{100P}{100 - P}$$

or, since P is a function of the temperature, say $F(t)$, which has already been determined,

$$S = \frac{100F(t)}{100 - F(t)}$$

In a solution supersaturated to s degrees the sugar per 100 of water will amount to $S + s$, and the percentage of sugar, p , in it will be given by

$$p = \frac{100(S + s)}{100 + S + s} = \frac{100 + F(t)(100/s - 1)}{1 + 100/s - F(t)/100} \dots \dots \dots (1)$$

It is well known that at a given temperature the refractive index of a sugar solution varies with the concentration. Assuming the fixed temperature to be 0°C . we may write

$$r = \theta_0(p)$$

where r is the refractive index, p the percentage of sugar in solution, and θ_0 the function for solutions at 0°C . It is equally well known that the refractive index of a solution of a given concen-

tration decreases with rise of temperature; and it may be that the rate of variation per degree is not the same for different concentrations of solution: for instance, it is not likely to be the same for zero concentration (pure water) as for a concentrated solution. The quantity, then, to be subtracted from $\theta_0(p)$ of the last equation in order to give the refractive index, not only of any strength of solution but for any temperature above 0°C ., will be a function of both the temperature and the concentration of solution, and may be written $\phi_0(t, p)$, where t is the temperature and ϕ_0 the function; the suffix indicates that it is appropriate to the θ function when the latter relates to 0°C . For brevity this function will be called the temperature coefficient. We have, then, for any concentration and any temperature,

$$r = \theta_0(p) - \phi_0(t, p)$$

The use of this equation would involve a knowledge of the refractive indices of highly concentrated solutions at 0°C ., and of their temperature coefficients starting from the same point. It is found, however, impossible to work with concentrated solutions at low temperatures owing to their tendency to crystallise, but they may readily be manipulated through a range of temperature, 30° to 75°C ., which is important industrially. Within that range, and within the industrially important range of concentrations, 72% to 81% of sugar, they have a temperature coefficient, say $\phi(t, p)$, which, it is found, can be expressed (keeping within errors of experiment) in a simpler way than could that of the larger range $\phi_0(t, p)$ which goes down to zero temperature and zero concentration. This simplified temperature coefficient involves a change in the other function which we will now call θ . By properly defining ϕ and θ , r may be expressed by these functions just as well as by the more complex functions ϕ_0 and θ_0 .

In the equation

$$r = \theta(p) - \phi(t, p) \dots\dots\dots (2)$$

$\phi(t, p)$ is the temperature coefficient of the refractive index correct (within errors of experiment) over a range of temperature 30°C . to 75°C . and a range of concentration 72% to 81%, while $\theta(p)$ is a function of the concentration such that (2) will give the refractive index, as found by experiment, for any solution at any temperature within the range specified.

Since, as we have seen (eq. 1), p may be expressed in terms of t and s , it is obvious, from eq. 2, that r also may be expressed in the same terms. Of the three quantities in eq. 2, the refractive index and the temperature can readily be ascertained at any time at the vacuum pan, whence the remaining quantity, the supersaturation, may be known. But, for this, it is of course necessary to know the functions $F(t)$, $\theta(p)$, and $\phi(t, p)$. The first of these has been carefully determined by Herzfeld, hence the object of this investigation was to ascertain the functions θ and ϕ .

To determine ϕ it was necessary to ascertain the refractive indices of a solution of known concentration at various temperatures, and then to deal in the same way with solutions of other concentrations covering the range above referred to. From this series of observations $\phi(t, p)$ was determined. In order to find θ it was necessary first to ascertain the refractive index of a solution of known concentration, p , at a definite temperature, the temperature chosen being about the middle of the range for which the temperature coefficient for that concentration of solution had been ascertained. If r_1 is the index thus found we have, from (2)

$$\theta(p_1) = r_1 + \phi(t, p_1) \dots\dots\dots (3)$$

This gives us one value of $\theta(p)$, viz., that for p_1 . By making similar determinations with other concentrations the function $\theta(p)$ was found.

It was thought that one set of readings for each

solution of different concentration should furnish data to derive both the functions. But it was found to be impossible to get thick solutions so homogeneous that a single sample placed in the refractometer could be relied upon accurately to represent the bulk. This did not matter so far as the determination of the temperature coefficient was concerned, for the results showed that the influence of concentration was trifling in comparison with the influence of temperature, and an error of even $\frac{1}{2}\%$ in the concentration would not be serious. But in determining the θ function accurate knowledge of the concentration was required. The investigation was therefore divided into two parts: (1) the determination of the temperature coefficients by placing in the refractometer one sample of each solution, and taking readings of its index at different temperatures; and (2) the determination of $\theta(p)$ by placing in succession in the refractometer, maintained at constant temperature, several samples of a solution of known strength, taking the mean of the index readings to be the true index, and repeating this process with solutions of various strengths.

Experimental.

An Abbé refractometer with jacketed prisms was used, the readings of which refer to the D radiation. The prisms were maintained at the required temperature by the circulation through their jackets of water from a thermostat.

The thermostat.—For a full description of this apparatus reference may be made to a paper by one of us on "Studies of the Processes Operative in Solutions, XXII.," Proc. Roy. Soc., A. 87, 1912.

As several alterations had to be made to fit the apparatus for the higher temperatures required in this investigation a brief description will be of use. The thermostat consisted of a lagged cylindrical tank holding about 60 litres of water, fitted with a stirrer and a rotary pump to circulate the water anywhere outside the vessel. Both these were driven by electric motor. This outside circuit consisted of the prism jackets of the refractometer and a glass bottle with inlet and outlet tubes so arranged that the circulation could be viewed. A thermometer was placed in the tank for convenience, though the temperatures recorded were those of the thermometer in the prism jackets. The heat required to maintain the temperature of the water was provided by an electric radiator lamp, taking 250 watts, immersed in the water. At the higher temperatures the supply of heat was augmented

FIG. 1.

FIG. 2.

by a Bunsen burner applied to a spiral copper tube through which water from the tank was caused to circulate by means of the pump. The regulation of the temperature was effected by the automatic making and breaking of the electric circuit containing the radiator lamp at intervals the length of which was controlled by the mercury regulator shown in Fig. 2, the lower part of which was immersed in the water of the tank. The side tube of the regulator is graduated with a temperature scale, so that when the level of the mercury is adjusted to a definite degree on this scale, the other level of the mercury will be at a convenient height in the finer capillary tube when the water in the tank has reached that temperature. Fine adjustment can then be made by raising or lowering the platinum wire in the capillary. This form of regulator can be rapidly and accurately set so as to act at any required temperature. The platinum wire in the capillary, and the other one sealed into the tube at *c*, were connected through a Leclanché cell and a Post Office relay of high resistance. As less than a milliamperé goes through this circuit the surface of the mercury in the capillary does not foul. The relay does not directly put the radiator lamp, which takes its current from the mains, in and out of action, but does so indirectly by means of another circuit in which a second relay, and certain branches and resistances, are arranged so as to prevent sparking in the P.O. relay, the final result being that when the mercury touches the platinum wire the radiator lamp goes out, and when it recedes from the wire the lamp lights up. The action of the regulating system is very reliable; it keeps a steady temperature well within 0.05°C . at the highest temperatures employed. Paraffin wax was put on the water in the tank to prevent evaporation. When it was desired to change the temperature quickly, the tank was partially emptied and then filled again with cold water, or with boiling water, and the regulator re-adjusted.

Preparation of the solutions.—The sugar used was made at the Chelsea sugar refinery, Auckland, New Zealand, from specially pure material. The crystals were well formed, and after effective washing with water in a centrifugal to remove all traces of mother-liquor, and after a preliminary drying, they were ground and passed in succession through gauze sieves of 30 and 36 holes to the linear inch; the material passing through the former and caught by the latter was used for the investigation. Before making a solution a quantity of this selected sugar was dried *in vacuo* at 100°C . The amounts of sugar and water necessary to make a solution of a desired concentration were weighed into a round-bottom flask of 160 c.c. capacity fitted with a two-holed indiarubber stopper. Through one hole was inserted a thermometer, the bulb reaching nearly to the bottom of the flask, and through the other a bent glass tube sealed at its lower end, but having a small hole in its side, as shown in Fig. 1. The stopper having been inserted, the pressure in the flask was rapidly reduced to one or two inches of mercury, and the valve tube raised so as to close the flask and retain the vacuum. This method of closing the flask left no cavities in which solution could lodge. It was ascertained that the process of evacuation did not, in the time, remove an appreciable amount of vapour from the water which had been weighed in. The sugar was dissolved in the water by heating the flask in a water bath, or, in the case of a concentrated solution, in a brine bath, at the same time keeping it in motion. To dissolve the sugar the contents of the flask were maintained some ten or fifteen degrees above saturation temperature. The solution was always milky at first owing to minute air bubbles, but boiling for a few seconds removed these completely. Brisk boiling was induced by pouring cold water on the upper part of the flask.

From this point the processes for determining the θ and ϕ functions differed.

Determination of temperature co-efficient.—The flask was now removed from the bath and the contents well mixed by alternately inverting the flask and giving it a circular motion. Air was then admitted by means of the valve tube, and the flask again closed. The stirring was continued for a short time, care being taken to trap no air bubbles, for these would interfere with the indications of the refractometer. The thermometer was then withdrawn from the stopper and quickly replaced by a previously cleaned and dried wash-bottle exit tube, but with no constriction at the end. The valve tube was then pushed down and used as a mouth tube, the flask being thus fitted like a wash bottle. Some of the solution was ejected into a receptacle immediately beside the open refractometer prisms, which were being maintained at the required temperature by the circulation through their jackets of water from the thermostat, and when about a quarter of the solution had come through, the stream was directed for an instant on to the lower prism, which was then immediately closed. If no bubbles were observed in the sample between the prisms the rest of the solution was dispensed with, and readings taken.

The readings.—The first temperature for which readings were taken was usually in the vicinity of the saturation temperature, and was the highest desired for the particular solution in the refractometer. After sufficient length of time to insure that the solution had attained the required temperature, the readings were taken. As there were two observers, the personal error was eliminated as far as possible by each making a series of five adjustments of the refractometer field without knowing the readings, which were made and recorded by the other observer. The average of these readings was the value adopted. The temperature was then lowered and another set of readings taken. After the lowest temperature required had been reached, the temperature was raised and readings taken at one or more points near previously observed temperatures. If the rising-temperature and falling-temperature observations proved consistent, *i.e.*, fell on the same curve when plotted, this was taken as an indication of the absence of crystallisation, and that sufficient time had been allowed for the prisms and solution to attain the temperature of the water in the jacket.

Determination of $\theta(p)$ function.—The procedure for the determination of $\theta(p)$ was somewhat different. The difficulty of getting concordant results from different samples of the same solution necessitated special precautions being taken. After the solution had been prepared, the flask was placed in a wire frame which could be rotated in an air bath in such a way that the flask was inverted during each revolution of the spindle. The bath was maintained at a temperature a few degrees above the saturation temperature of the solution. After thorough mixing in this way the flask was taken out of the bath, air admitted to it, the thermometer withdrawn and replaced by a wash-bottle tube, rather long in the bent portion, and without constriction at the end. A small quantity of the solution was ejected by operator A into a receptacle beside the open prism, and the stream then directed for an instant on to the prism, which was immediately closed by operator B. In the meantime, operator A had kept the stream going very slowly until B had time to insert into the open end of the tube a previously prepared indiarubber plug. The flask was then replaced in the air bath until another sample was required. For receiving the sample the refractometer was placed so that the clear glass surface of the refracting prism was uppermost, and the sample

fell immediately on this; and not, as is usual, on the ground surface of the other prism. In this way the surface of the solution which was to form the interface between glass and solution was exposed to the air for the least possible time. After a set of readings by the two operators, as before described, the prisms were thoroughly cleaned and another sample from the flask placed in the instrument. The procedure was the same as before, except in one particular. Operator A removed the flask from the air bath and created a slight pressure in the flask by means of the mouth tube, whilst operator B cut about half an inch off the end of the exit tube, so as to expose a clean place to the issuing liquid. Each subsequent sample was taken in this way. All samples from one solution were brought to the same temperature in the refractometer before readings were taken. This temperature was usually ten to fifteen degrees below the saturation temperature.

Corrections.—The thermometer entering the prism jacket, on which the temperatures were read, was standardised by comparison with a standard thermometer. The two were placed with their bulbs together, the standard being vertical and the other horizontal as it is in the instrument, in a glass vessel through which water from the thermostat was made to circulate; a series of readings of both thermometers was taken.

The refractometer was tested several times during the course of the investigation by using the glass test plate supplied with the instrument. No variation was detected. No correction has been made for the varying temperatures of the glass prisms.

Since sugar and water were weighed into the flask at room temperature, while the samples for the refractometer were taken from the flask when it was a few degrees above the saturation temperature of the solution, the vacant space in the flask would then contain vapour which must have been taken from the solution. It is estimated that the maximum correction to the concentration on this account would not exceed 0.03% of sugar in solution.

A correction operating in the opposite direction is that for buoyancy of the air in weighing; the maximum effect here being 0.01%. Both these corrections have been neglected.

Results.

As before mentioned the investigation was divided into two parts, the first of which had for aim the determination of the temperature coefficient of the refractive index. A sample of the results obtained in determining this function is shown in the following table:—

Concentration of solution taken, 78.37% sugar.

Temperature.	Index found.	Calculated.	Difference.
74.3°	1.47486	1.47489	0.00003+
69.7°	1.47801	1.47793	8—
48.5°	1.48063	1.48066	3+
61.4°	1.47783	1.47778	5—
73.5°	1.47500	1.47507	7+

The last two readings were taken after the solution had reached its lowest temperature and had been re-heated.

On plotting the values found (column 2), the index of refraction was seen to be, within errors of experiment, a linear function of the temperature for this range of temperatures. The formula which best fits the results is

$$R = 1.49150 - 0.0002235t$$

where R is the refractive index for this particular concentration of solution, and t the temperature. The figures in column 3 are derived from this formula, and column 4 gives the differences between the calculated and experimental values.

Results for nine different concentrations of solution were tabulated in a similar way. In every case a linear function satisfactorily represented the relation between temperature and index, and an empirical formula was found for each strength of solution. The differences between the indices calculated from these formulae and the values actually found were of the same order as those shown in the above example. Fifty-two observations, each one the mean of ten readings, as before explained, were taken in all; and in only two cases did the difference between the observed and calculated values reach the fourth decimal place, the larger of the two differences being 0.00024. We think this affords evidence that the Abbé refractometer is capable of a high degree of accuracy if used in the manner above described.

The relations between temperature and index of refraction for different strengths of solution, as found experimentally, are plotted in Fig. 3, where the numbers correspond to those in the first column of the table below. The lines drawn in the

FIG. 3.

figure correspond to the empirical formulae found. The circles with strokes pointing upwards indicate observations taken on re-heating the solution; the

circles without strokes, and those with strokes pointing downwards, indicate observations taken before re-heating.

To arrive at the temperature coefficient it is not necessary to know the constants in the empirical formulae, and indeed these constants could not be relied upon since the exact concentrations of the solutions were, for reasons already given, doubtful. The following table gives the approximate concentrations, p , of the nine solutions dealt with; and the "coefficient of t " found for them. The meaning of this last expression will be clear on referring to the last equation; it is the co-efficient of t for a particular strength of solution, not that for any strength $-\phi(p, t)$.

No.	p .	Co-eff. of t .
1.....	72.5	0.000216
2.....	73.5	218
3.....	74.8	2203
4.....	75.0	2183
5.....	75.4	218
6.....	76.3	2217
7.....	77.0	2197
8.....	78.4	2235
9.....	79.5	2252

On plotting this relation it is found to be linear, within errors of experiment, and to be given by coeff. of $t=0.0001241+0.000001267p$ which gives, as the temperature coefficient of the refractive index,

$$\phi(p, t) = (0.0001241 + 0.000001267p)t \dots (4)$$

Estimation of $\theta(p)$.—Knowing the temperature coefficient from eq. 4 we can, with the help of eq. 3, find $\theta(p)$ by carefully determining the refractive indices of a number of solutions of different concentration, each at a different temperature. The results obtained for one of these solutions are given in the following table:—

Strength of solution, 74.55%.

Temperature, °C.	Index found.
50.3	1.47056
50.3	1.47040
50.3	1.47015
50.3	1.47071
50.3	1.47064
Mean	1.47051

The temperature coefficient at 50.3° C. is, from eq. 4, 0.0002185. The value of $\theta(p)$ for $p=74.55$ will, therefore, be given by $\theta(p)=1.47051+(0.0002185 \times 50.3)=1.48150$.

Each of the observations recorded in the above table is of a different sample of the solution, and is the mean of ten readings as already described. The discrepancy between the highest and lowest of these observations is 0.00056, a figure much beyond the instrumental or personal error, and arises from differences in the concentration of different samples which persisted in spite of the endeavours made to obtain a homogeneous solution. The following table gives the values of $\theta(p)$ obtained for ten different solutions, the number of separate samples observed in the case of each solution, and the maximum discrepancy between observations:

p .	$\theta(p)$ from exp.	No. of obs.	Max. discrep.	$\theta(p)$ from plot.	Diff.
72.51	1.47605	4	0.00061	1.47604	0.00001—
73.52	1.47858	4	26	1.47870	12+
74.55	1.48150	5	56	1.48141	9—
75.46	1.48378	5	60	1.48380	2+
75.27	1.48603	6	88	1.48593	10—
77.54	1.48953	5	113	1.48927	26—
77.55	1.48806	4	58	1.48930	34+
78.41	1.49147	4	37	1.49156	9+
79.47	1.49433	4	41	1.49435	2+
80.74	1.49729	5	98	1.49716	13—

The figures in the fifth column are calculated from the following empirical equation which was found to fit the results:—

$$\theta(p) = 1.28534 + 0.00263p \dots (5)$$

and the numbers in column 6 show the differences between the values derived, as before explained, from experimental results and those derived from the above equation.

In Fig. 4 the numbers in column 2 are plotted against percentage of sugar; the line represents the relation expressed by eq. 5.

The refractive index of any sugar solution between the before-mentioned limits of concentration and of temperature is, then, given by

$$\begin{aligned} r &= 1.28534 + 0.00263p - \\ &\quad (0.0001241 + 0.000001267p)t \\ &= 1.28534 - 0.0001241t + \\ &\quad (0.00263 - 0.000001267t)p \dots (6) \end{aligned}$$

where r is the refractive index, p the percentage of sugar in solution, and t the temperature in Centigrade degrees.

The following table will facilitate the computation of refractive indices from this equation. To find the refractive index of a sugar solution between 72% and 81% concentration at a given temperature, multiply the % concentration of the solution by the "coefficient of p " for that temperature and add the product to the figure in line with that temperature in the second column. For example, if we have a 75.6% solution at 41° C. the refractive index will be $1.28026 + (75.6 \times 0.002578) = 1.4752$. The decimal places have been extended for purposes of calculation, but in the result no figures after the fourth decimal are reliable.

Table to be used with equation 6.

Temp. °C.	Value of $1.28534 - 0.0001241t$	Co-efficient of p .
34	1.28112	0.0025869
35	1.28100	0.0025857

68	1.27690	0.0025438
69	1.27677	0.0025426
70	1.27665	0.0025413
71	1.27652	0.0025400
72	1.27640	0.0025388
73	1.27628	0.0025375
74	1.27616	0.0025362

To express the refractive index in terms of temperature and supersaturation we have to replace

p in the last equation by its value as given in equation 1, and we then have

$$r = 1.28531 - 0.0001241t + \frac{100 + F(t)(100/s - 1)}{1 + 100/s - F(t)/100} (0.00263 - 0.000001267t) \quad (7)$$

where $F(t) = 64.1835 + 0.13477t + 0.0005307t^2$ as found by a careful determination by Herzfeld (Z. ver. deuts. Zuckerind., 42, pp. 181, 232).

sugar in the saturated solutions: this table is calculated from the last equation. Its use may be illustrated as follows: If a sugar solution at 145° F. is found to have a refractive index of 1.4727, then it is supersaturated to the extent of 30°.

The research described in this paper was carried out at Auckland University College, Auckland, New Zealand.

FIG. 4.

In eq. 7 are given the relations which it was the object of the investigation to determine.

Since the Fahrenheit scale is used in British sugar factories it is convenient to express the results in that scale. The relation between the scales is given by $t = 5u/9$, where t = centigrade degrees, and u = Fahrenheit degrees in excess of 32. Herzfeld's relation then becomes $f(u) = 64.1835 + 0.07487u + 0.0001638u^2$, and eq. 7 becomes

$$r = 1.28531 - 0.00006894u + \frac{100 + f(u)(100/s - 1)}{1 + 100/s - f(u)/100} (0.00263 - 0.000000704u).$$

Appended is a table giving refractive indices for steps of 5° temperature and 10° in supersaturation, with an added column giving the percentage of

Communication.

THE MANUFACTURE OF NITRIC ACID FROM NITRE CAKE.

BY DR. J. GROSSMANN.

Dr. GROSSMANN writes as follows in reply to Captain Goodwin's criticism (this J., 1917, 1161) of his paper on the manufacture of nitric acid from nitre cake (this J., 1917, 1035):—

Captain Goodwin has failed to understand that in the working of the two patent processes which are described in my paper, no agitation or stirring is required; they are baking operations which can be carried out in any shallow muffle. The use of mechanical stirring apparatus would only add to the cost without improving the efficiency of my processes, as the latter give quantitative results without stirring.

I have dealt with nitre cake from different works, and so far as my experience goes it varies in its content of free sulphuric acid between 27 and 33%. Though difficult in laboratory experiments, it will be an easy matter on a large scale to adjust the mixture of nitre cake and sodium nitrate in such a manner as to yield a saltcake containing less than 2% of free acid. The assumption that the mixture containing coke might lead to fires is quite erroneous, as is the statement that there is no advantage in adding carbonaceous matter. The two processes, i.e., the one with and the other without the addition of carbonaceous matter, are designed to suit different purposes. The condensation of the nitrous gases can be effected in such manner as to add very little to the cost, certainly not more than a small fraction of what a mechanical furnace such as Captain Goodwin recommends would cost in material, working, and upkeep.

I agree that saltcake has not always been profitably saleable; but Captain Goodwin appears to have overlooked the fact that in the manufacture of hydrochloric acid from nitre cake nearly 3 tons of saltcake is produced against one ton of saltcake produced in the manufacture of nitric acid by my process, so that the manufacturer of hydrochloric acid would be far more seriously handicapped by a slump in saltcake. By the adoption of my process in nitric acid making, nitre cake would be produced only as an intermediate product

in like manner as it has always been an intermediate product in the manufacture of saltcake in connection with the Leblanc process, and thus cease to be a marketable commodity for the manufacture of hydrochloric acid.

It is quite fallacious to represent the reactions between nitre cake and sodium nitrate, and nitre cake and sodium chloride, as if they were technically analogons. Complete decomposition in a mixture of nitre cake and sodium nitrate takes place at a temperature below 250°C . and is assisted by the fact that sodium nitrate melts at 330°C ., whereas a mixture of nitre cake and sodium chloride requires a temperature of nearly 500°C . for its decomposition, *i.e.*, a temperature which is still 350°C . below the melting point of sodium chloride. It is therefore evident that sodium nitrate is technically more amenable to treatment with nitre cake than sodium chloride; and whilst the working costs are higher in the production of hydrochloric acid, the absolute profit, owing to the low intrinsic value of hydrochloric acid, is less than in the production of nitric acid. The present absurdly inflated price of hydrochloric acid is no legitimate basis on which to form estimates of profit.

I cannot agree with Captain Goodwin's remark "that my process might be remunerative only whilst the war lasted." I have shown that under any conditions processes for the manufacture of hydrochloric acid from nitre cake are technically

and commercially at a disadvantage; and it may be safely predicted that after the war, when competition will be the determining factor in manufacturing, any process which will enable the manufacturer to produce nitric acid cheaper will be found acceptable.

As regards present conditions I may say that my aim in working out my processes has been to stop the great waste of sodium sulphate and sulphuric acid which takes place when nitre cake is used in the place of weak acid; and the still greater waste where large quantities of nitre cake are lying useless. All this waste entails additional importation of large quantities of pyrites from Spain and consequent loss of gold, foodstuffs, and shipping room to this country—matters which will be serious for years after the war and which should be taken in hand in time by the Government and properly dealt with.

The rational utilisation of nitre cake is not only a chemical but an economic problem of national importance, and its solution will only lie in methods which effect a commensurate saving in the use of pyrites. Most of the methods used at the present time are makeshifts which in the fourth year of the war should be overhauled. But unless the Government recognises this there is no inducement in the present times to manufacturers to take up new processes on these lines, however profitable they might be.

STUDIES IN NITRIDE FORMATION.

BY E. R. MAXTED, PH.D., R.S.C.

The general chemical inertness of free nitrogen under ordinary conditions lends a peculiar interest to the study of the methods which must be employed in order to induce nitrogen to combine directly with other elements. Broadly speaking, and omitting for the time being any consideration of a few nitride-forming elements such as lithium, nitrogen only becomes active at moderate temperatures in the presence of a catalyst. Two industrial reactions, at least, take advantage of this property, namely the synthesis of ammonia by the Haber process and the direct formation of cyanides by interaction of alkalis, carbon, and nitrogen, the catalyst usually employed being in each instance iron.

Nitrogen, however, acquires considerable chemical activity at high temperatures, possibly owing to its dissociation, the compounds formed being in some cases capable of stable existence throughout the entire range of temperature between the temperature of formation and room temperature, while in others the product is only obtained at the ordinary temperature by cooling sufficiently quickly through an intermediate temperature zone in which the compound is liable to decomposition. The commercial formation of nitric oxide offers an example of this method of working, it being found necessary, in order to obtain optimum yields of nitric oxide, to "freeze" the equilibrium by cooling quickly from the temperature of the high tension arc to 1000° C., below which temperature nitric oxide is able to exist in a state of false stability.

Nitric oxide is, however, peculiar in properties by reason of the slowness with which it decomposes even at high temperatures, and in the case of other nitrogen compounds a far more rapid form of cooling is necessary in order to recover at ordinary temperatures the compounds formed for instance at the temperature of the arc.

I propose to consider in the present paper firstly an interesting aspect of the formation of ammonia from mixtures of nitrogen and hydrogen. It is well known that by the action of a catalyst at temperatures varying from 400° to 800° C., small amounts of ammonia are obtained at atmospheric pressure; further, that the yield may be increased by working at an elevated pressure, the volume of ammonia formed being found to be, for small percentages, approximately proportional to the pressure.

It is known, however, that ammonia may also be formed, in a similar manner to nitric oxide, by subjecting a mixture of nitrogen and hydrogen to the action of induction sparks, and it was therefore thought interesting to investigate further the possibility of forming ammonia thermally.

The subject has been examined experimentally in the work about to be described, and it will be shown that yields of ammonia amounting to over one per cent, by volume for atmospheric pressure may be obtained thermally by sufficiently intense cooling of mixtures of hydrogen and nitrogen from very high temperatures to the temperature of the room. The result is of special interest if one considers that such a result is only obtainable otherwise below 350° C., a temperature at which ammonia formation, even in presence of active catalysts, does not take place with measurable velocity.

Before passing to a description of the methods employed I propose to deal very briefly with the

theoretical aspect of ammonia formation at high temperatures.

All the formulae which are derivable by thermodynamic treatment of the ammonia reaction depend on more or less small differences between the specific heats of nitrogen and hydrogen on the one hand and of ammonia on the other. It is only possible to determine the values of these specific heats, and of their temperature coefficients, at low or at the most at moderate temperatures and to extend by extrapolation these experimental results to higher temperatures, assuming that no latent factors which will cause an increase or decrease in the observed temperature coefficients appear with increasing temperature. It is known, for instance, that the specific heat of a gas may be expressed by the general relation, $C = a + bT + cT^2 + dT^3$ etc., but the coefficients of powers of T higher than T^2 are too small to be determined at temperatures for which the specific heat is capable of direct measurement. It is, however, just these higher powers of T which will become, with increasing temperature, more and more important factors in the determination of the equilibrium ammonia content. Assuming a linear temperature coefficient $a + bT$ for nitrogen and hydrogen and a coefficient of the form $a + bT + cT^2$ for ammonia, this being merely the mathematical expression of experimentally observed results, the following three alternative equations are obtained, in which—

$$K = \frac{P_{NH_3}}{P_{N_2}^{\frac{1}{2}} \times P_{H_2}^{\frac{3}{2}}}$$

- (1) $\log_{10} K = \frac{2215}{T} - 3.625 \log_{10} T + 0.000307T + 0.29 - 10^{-6}T^2 + 1.82$
 (2) $\log_{10} K = \frac{2098}{T} - 2.5088 \log_{10} T - 0.0001006T + 0.186 - 10^{-6}T^2 + 2.1$
 (3) $\log_{10} K = \frac{2098}{T} - 2.806 \log_{10} T + 0.0000932T + 0.145 - 10^{-6}T^2 + 2.8494$

The first two equations are due to Haber, equation (1) being based on Wüllner's and Wiedemann's values for the specific heat of ammonia and on Thomsen's figures for the heat of formation, while equation (2) is based on Haber's own measurements. The third equation has been derived by the author by independent calculation based principally on Haber's experimental results.

All three equations agree in that they all contain terms which cause the equilibrium content first to sink with increasing temperature, then to pass through a minimum and finally to increase once more, but the calculated position of the minimum and the rate of increase vary with the formula employed for the calculation. On extending these formulae, which all represent more or less correctly the ammonia equilibrium at temperatures usually employed for the synthesis of ammonia, to high temperatures, widely different results are obtained and the discrepancy between Wiedemann's, Wüllner's, and Thomsen's results for the specific heat and for the heat of formation of ammonia on the one hand, and of Haber's measurements on the other, suggest a careful experimental revision of these important quantities.

The following table gives the variation of K with temperature by each of the formulae quoted.

TABLE I.

Temperature, ° A.	Value of $K \times 10^4$.		
	By eq. (1).	By eq. (2).	By eq. (3).
1000	5.7	5.7	5.8
2000	0.78	0.26	0.25
3000	3.03	0.28	0.03
4000	152.0	1.5	0.9

The formation of ammonia by the action of sparks on a mixture of nitrogen and hydrogen was first observed by Deville and later studied by Donkin, who showed that such a mixture sparked in an eudiometer over dilute acid gradually disappeared, the formation taking place in presence of sparks only and not by the action of a silent discharge. This method of synthesis appeared to confirm the possibility of forming ammonia thermally, but since it is difficult by means of spark discharge to heat the whole of a definite volume of gas uniformly to a known high temperature before suddenly cooling, and in view of the comparatively low yields—probably due to this—obtained by sparking in similar reactions, for instance in the synthesis of nitric oxide from nitrogen and oxygen, it was not thought to constitute a promising method for the production of maximum quantities of ammonia. I considered it therefore preferable to investigate the formation of ammonia firstly by rapidly cooling mixtures of nitrogen and hydrogen injected into flames, and secondly by rapidly cooling such gas mixtures from the temperature of the high tension arc.

FIG. 1.

Accordingly, working by the first of these two methods, the thermal formation of ammonia has been studied, firstly for not extremely high temperatures, by rapidly cooling mixtures of nitrogen and hydrogen from the temperature of the oxy-hydrogen flame down to room temperature. The method of heating and suddenly cooling con-

sisted in injecting the mixture into an oxy-hydrogen flame burning under water, or, in a second series of experiments, in a water-cooled silica tube, the amount of ammonia being estimated in some cases by direct titration and in others colorimetrically by Nessler's solution. The reaction mixture contained, therefore, in addition to nitrogen and hydrogen, a volume of steam depending on the proportion of the mixture of nitrogen and hydrogen injected into the flame.

It was noted further that the yield of ammonia recovered at ordinary temperature was considerably greater when direct cooling with water was employed than when the flame was cooled by contact with a water-cooled quartz tube.

The apparatus used for the first series of experiments is illustrated in Fig. 1. It consisted of a silica combustion chamber, A, 6.5 mm. in diameter and 7.5 cm. in length, completely immersed in about 900 c.c. of distilled water contained in a glass vessel, B, fitted with an efficient cooling coil, C, through which a rapid current of cooling water was passed, the vessel having a capacity of slightly more than one litre. Into the quartz reaction chamber, nitrogen, hydrogen, and oxygen, at rates determined by velocity meters, were injected and ignited, the flame gases passing out of the open end of the combustion chamber and into the water, by the action of which the ammonia, recovered from the flame by sudden cooling, was retained. In some cases the water was replaced by dilute acid, without, however, any appreciable difference in the results, provided that the water was kept cool. The amount of oxygen passed into the reaction chamber was in every case regulated in such a way as to leave uncombined hydrogen equal to three times the volume of the nitrogen passed in.

In order to obtain a comparison of the results obtained at various temperatures and at varying partial pressures, i.e., by the increasing dilution of the oxy-hydrogen flame with a mixture of nitrogen and hydrogen, advantage was taken of the known fact that for small percentages of ammonia, the volume formed at a given temperature is directly proportional to the pressure, so that the volume of ammonia which would be formed at the temperature of the flame but at atmospheric pressure may be calculated by dividing the value observed by the corresponding partial pressure of the nitrogen-hydrogen-ammonia in the nitrogen-hydrogen-ammonia-steam reaction mixture. In this way it becomes possible easily to compare the relative amounts of ammonia formed at different temperatures and at varying partial pressures. In this series of experiments the ammonia determination was made colorimetrically by Nessler's reagent in the resulting solution in the cooling water, care being taken to use for cooling the flame distilled water free from ammonia. In those cases in which dilute acid was used for cooling, this was made up by dissolving 40 c.c. of ammonia-free N/10 sulphuric acid in each litre of distilled water.

Table II. summarises the results obtained by direct cooling with water or dilute acid.

TABLE II.

Expt. No.	N.	H.	O.	Duration of expt. (mins.).	Vol. % of NH_3 in N/H mixture.	Partial pressure of system N-H- NH_3 in flame.	Estimated flame temp., ° Abs.	Vol. % of NH_3 formed at absolute pressure of 1 atm.
1.	60	220	20	15	0.00235	0.86	1280	0.0027
2.	60	260	40	15	0.005	0.75	1500	0.0067
3.	60	360	90	15	0.013	0.57	1830	0.023
4.	30	270	90	15	0.018	0.4	2120	0.045
5.	20	210	90	15	0.0205	0.31	2260	0.066
6.	20	300	120	10	0.0366	0.25	2350	0.146
7.	20	460	200	5	0.07	0.167	2470	0.42
8.	10	430	200	5	0.112	0.091	2580	1.23

The columns headed N, H, and O represent the velocity in litres per hour of the nitrogen, hydrogen and oxygen passed into the reaction chamber. For experiments Nos. 2, 3, 4, and 5 the cooling agent was water, otherwise dilute sulphuric acid was used.

It will be noticed that the percentage of ammonia by volume in the nitrogen-hydrogen mixture recovered by suddenly cooling (reduced for uniformity to 1 atmosphere pressure) rises from 0.0027 to 1.23 as the reaction temperature approaches that of the oxy-hydrogen flame. The theoretical temperature of the oxy-hydrogen flame calculated by equating the integrated product of the heat capacity of the gases involved, expressed as a function of temperature, multiplied by the temperature, against the heat of formation of water, works out, if dissociation effects be taken into consideration, at something over 3000° C., but in practice, since the complete combination of oxygen and hydrogen is not absolutely instantaneous, radiation phenomena will interfere not only with the rate of fall of the maximum temperature but also with the value of this maximum temperature itself, at any rate as far as the gross maximum temperature of the flame is concerned.

In the absence of sufficient data to calculate the effect of such radiation, I have inserted in the column headed "Flame temperature" values obtained by interpolation from Fery's experimental measurements of the temperature of the oxy-hydrogen and hydrogen-air flames.

Experiments with indirect cooling.

The reaction chamber taken for this series of experiments consisted of a vertical quartz tube 90 cm. long and 8 mm. in internal diameter. This was cooled by making it the inside tube of a long Liebig condenser. The flame gases, which were in this case cooled only by contact with the cold walls of the silica tube, were allowed to pass from the bottom of the tube through a known quantity of N/10 acid, which was afterwards titrated back with alkali in the usual manner. As was to be expected from the less rapid cooling, the results obtained were at high temperatures less than those obtained by directly leading the flame into cold water. At lower temperatures the divergence became less marked, until, at the lowest temperature studied, approximately equal values for the yield of ammonia were observed. The results obtained by indirect cooling in the above manner are summarised in Table III.

TABLE III.

4.	30	0.167	0.0196	2470	0.118
5.	30	0.091	0.019	2580	0.21

In the method of sudden cooling above described there is certainly the possibility that ammonia was formed not by direct synthesis but secondarily by the reduction of nitric oxide by the excess of hydrogen, it being well known that mixtures of oxygen and nitrogen at the temperature of the oxy-hydrogen flame give rise to nitric oxide. This secondary formation of ammonia is not, however, probable since, firstly, if such mere reduc-

tion of nitric oxide to ammonia took place at high temperatures, and if the ammonia equilibrium did not have an increased value at such high temperature, the system would pass under conditions in which equilibrium is established practically simultaneously, from an equilibrium state into non-equilibrium, this being contrary to experience, and, secondly, if the reduction took place at low temperatures (below 350° C.), so that the ammonia formed was in equilibrium at the time of its formation, the amount of ammonia formed would be increased by decreasing the rate of cooling, nitric oxide being capable of being recovered practically undecomposed even by less rapid cooling than the slower method used in the above experiments. Such an increase in the amount of ammonia with decreased rate of cooling is in direct opposition to experimental evidence, and in any case the reduction of nitric oxide to ammonia by free hydrogen in the absence of a catalyst does not take place at the temperature (below 350° C.) at which the ammonia observed would be formed in equilibrium, especially in view of the extremely short time for which such temperature persists.

The results obtained would thus appear to form some ground for the view that the ammonia equilibrium at high temperatures increases more rapidly than can be deduced by assuming at such high temperatures a uniform change in the specific heat of ammonia, based on a relation of the simple form $a + bT + cT^2$ obtained by measurements at low temperatures; moreover the equilibrium capable of being calculated by such low temperature formulae may possibly be affected also by dissociation effects. I am at present examining the formation of ammonia by very rapid cooling of the high tension arc flame burning in nitrogen and hydrogen, the results of which investigation will, if war conditions permit, be published in the near future.

Nitride of iron.

Nitrides of easily reducible metals possess a special interest technically, since a direct synthesis of such a nitride would afford the possibility of a process for the manufacture of ammonia by alternately treating, firstly, the metallic oxide with a reducing gas containing nitrogen, such as producer gas, and, secondly, treating the nitride thus formed with steam, with formation of ammonia and regeneration of oxide. Examples have already been given of the use of iron for the catalytic activation of nitrogen at moderate temperatures, for instance in the formation of ammonia and of cyanides. It was therefore considered interesting to investigate the possibility of finding conditions for the direct synthesis of iron nitride from iron and nitrogen, the iron acting both as catalyst and as nitride-forming element.

Iron nitride may, as is well known, be readily formed by leading a current of gaseous ammonia over reduced iron at an elevated temperature, preferably at about 460° C. On heating the grey powder thus obtained, either in a vacuum or in an inert gas, decomposition into iron and nitrogen begins at about 500° and is rapid at 600° C.

It should, however, be possible on theoretical grounds to reverse the dissociation represented by the equation $\text{Fe}_3\text{N}_2 = 4\text{Fe} + \text{N}_2$ and thus to effect a direct synthesis of iron nitride, by treating finely divided iron—in the presence of which nitrogen is known to become activated—with nitrogen at a higher pressure than the dissociation pressure of iron nitride and at a temperature just above its normal decomposition point.

The furnace employed for this work has proved of very general utility for experiments at elevated pressures not only with nitrogen but also with other gases, and is therefore illustrated here

(see Fig. 2). It consists of a cylindrical steel vessel of the shape shown, closed by a flanged recessed cover provided with a lead jointing ring fitting into the recess. The electric furnace contained in the steel bomb was fastened rigidly to two short copper rods passing through the cover and insulated from this by the arrangement shown, these rods functioning both as furnace supports and as leads for the heating current. The lower part of the inside tube of the electric furnace contained a short piece of silica tube closed at one end and holding a platinum/platinum-rhodium thermocouple. The ends of this couple were taken round the outside of the furnace and through the cover by way of insulated stuffing-boxes rendered gas-tight by vulcanite fibre. The electric furnace contained, in addition to the pyrometer, the charge of finely divided iron, preceded and followed by rolls of fine copper gauze in order to prevent any possibility of oxidation.

FIG. 2.

Gaseous nitrogen at a high pressure was introduced through the gas inlet, the furnace being immersed in water during each experiment. With the apparatus described I carried out a series of experiments at 100 atmospheres pressure and at various temperatures between 500° and 700° C. In no case was any trace of nitride obtained, showing either that the dissociation pressure of iron nitride lies above 100 atmospheres for the temperature region studied, or that iron itself is not a sufficiently active catalyst for the promotion of the reaction.

In consequence of this result, experiments were begun to measure, if possible, the dissociation pressure of iron nitride just above its normal decomposition point, or at any rate to determine whether this dissociation pressure is greater than that at which a commercial synthesis would be possible, this limit being probably about 200 atmospheres.

The method of investigation employed consisted in preparing a stock of iron nitride by the action of ammonia on iron and studying the pressure which is capable of being developed by the decomposition of this nitride in a closed system of small dimensions. For each experiment about 20 grms. of freshly prepared iron nitride, previously heated for one hour in a vacuum at 200° C., to expel any ammonia, was introduced into a steel tube, 1 cm. in internal diameter and 140 cm. long, provided with

two steel rods each 54 cm. long, loosely fitting into the tube. These steel rods served to fill up dead space on each side of the charge of nitride and also to ram the charge into a compact cake situated in the centre of the tube. This steel tube was closed at one end by a pressure gauge and at the other by a needle valve through which nitrogen could be introduced in order to raise the initial pressure to that required. The apparatus was remarkably gas-tight in that, in spite of its small dimensions, a pressure of, for instance, 200 atmospheres was usually capable of being retained overnight without sinking more than from one to two atmospheres.

In order to raise the nitride to the desired uniform temperature, a piece of 3-in. steel shafting about 15 inches long and bored longitudinally in such a way that the steel tube just slid into it, was slipped over the decomposition tube and the whole heated in a furnace, the temperature being measured by a pyrometer passed into a second hole in the steel shafting.

In order to displace air, nitrogen under pressure was alternately admitted to the system and blown away, this being repeated several times. The nitrogen was adjusted to the initial pressure required for the particular experiment, whereupon the needle valve was closed and heating begun, the temperature being gradually raised to 600° C. and maintained at this value for several hours, any abnormal increase in pressure other than the uniform rise due to expansion being noted. Finally the system was once more allowed to cool and the pressure was once more read.

The following temperature/pressure curves (Fig. 3) are typical of the results obtained, and

FIG. 3.

demonstrate the theoretical impossibility of synthesising iron nitride from iron and nitrogen, at any rate under the temperature and pressure conditions studied.

DISCUSSION.

The CHAIRMAN asked what explanation could be given of the part played by iron as a catalyst in bringing about the combination of nitrogen and hydrogen. Did the active modification of Strutt play any part in any processes in which nitrogen combined with other elements?

Dr. D. F. TWISS, referring to Dr. Maxted's classification of processes for the combination of nitrogen and hydrogen into those dependent on the influence of a catalyst and those involving a primary activation of the nitrogen, enquired whether the remarkable power of leguminous plants to convert atmospheric nitrogen into compounds could be definitely allocated to either of these groups. He also asked whether the formation of ozone when a glowing Nernst filament was immersed in liquid oxygen was quite on a par with the production of ammonia from nitrogen and hydrogen as effected in Dr. Maxted's investigation because, although the formation of ozone in the former experiment was doubtless in the main a thermal one, it was likely that the ultra-violet portion of the radiation from the filament might play an appreciable part. Regarding the combustion of a mixture of hydrogen and oxygen in the presence of nitrogen, Dr. Maxted had apparently disregarded the possibility of formation of ammonium salts; as the combination of hydrogen and oxygen was only partial at the temperature of the oxy-hydrogen flame, and as at the same temperature oxygen and nitrogen could react yielding a little nitric oxide, it was possible that the rapidly cooled gaseous mixture would contain a little nitric oxide and oxygen or nitrogen dioxide so that the final aqueous solution might contain not only ammonia but ammonium salts such as the nitrate. Indeed, under the conditions of experiment, the possibility of the formation of some nitric acid by oxidation of part of the ammonia itself during the period of cooling did not seem to be altogether excluded.

Mr. W. H. PATTERSON enquired whether the author had tried methods of cooling other than by means of water. He pointed out that the cushion of steam which would surround the flame would probably act as a heat insulator. He suggested that cooling by means of a cold metal surface would be quicker and therefore more effective. Having spent 18 months in Haber's laboratory in Germany he had seen the early work carried out by him on the direct synthesis of ammonia from hydrogen and nitrogen. Early results of this work had been most unpromising; it was only when it had been realised that pressure played such a part in the equilibrium that progress had been made.

Dr. S. R. CARTER enquired whether any evidence had been found of the presence of nitric oxide in the cooling water. It seemed to him that the conditions were ideal for its formation. What was the proportion of nitric oxide to the total amount of ammonia in the cooling water?

Mr. MANLEY suggested cooling by causing the flame to impinge upon a block of ice. Steam would not be formed.

Mr. E. C. ROSSITER pointed out that it was possible easily to get a pure iron, over 99%. Some years ago when experimenting he obtained specimens containing approximately only 0.2% of oxygen, but he had not succeeded in getting iron entirely free from oxygen. That fact might have considerable influence on the decomposition of the iron nitride.

Dr. H. W. BROWNSDON recalled the fact that Ramsay had used lithium for the absorption of nitrogen. He asked what other nitrides besides that of iron had been examined with a view to possible practical application.

Mr. F. H. ALCOCK observed that Rayleigh and

Ramsay had used magnesium for the absorption of nitrogen when they were preparing argon.

Dr. MAXTED, in reply, said that Dr. Morrell had raised an interesting point as to the function of a catalyst. We needed to know more, however, of what a catalyst really was. It was noteworthy that only those metals that formed, for instance, unstable hydrides were capable of activating hydrogen. Similarly in regard to the formation of nitrides, only those metals which formed unstable nitrides were able to activate nitrogen. Thus, iron only acted as a catalyst at temperatures higher than the decomposition point of its nitride. It was generally found that a catalyst must not form a stable compound with the substance to be handed on. He was unable to answer Dr. Twiss' question as to catalytic power of plants. As to the thermal formation of ozone, the yields of the latter obtainable by using liquid oxygen for the sudden cooling, were almost equal to those capable of being calculated thermodynamically from the ozone-oxygen equilibrium. He thought not only that the formation of ammonium salts together with ammonia in the cooling water was possible, but that there was good reason to think that that was the case. Small traces even of soluble gases were usually capable of passing through several wash bottles without absorption, whereas in these experiments absorption either by water or by dilute acid gave practically identical results. He had cooled the gases by sweeping into water-cooled capillaries, but at present he could not publish the results. Cooling by ice was not much more intense than with rapidly cooled water because even on ice the cooling surface consisted of a film of water covered by a film of steam caused by contact with the flame. A large number of metals formed nitrides directly; but he was interested specially in the formation of nitrides of easily reducible metals. The object was to find a nitride that could be formed directly by the action of producer gas on a metallic oxide at a moderate temperature. It was possible to get a good yield of nitride directly from manganese and chromium but the temperature of reduction of the oxides was too high for the purpose desired.

Glasgow Section.

Meeting held at Glasgow on Saturday, January 26th, 1918.

MR. JAMES MACLEOD IN THE CHAIR.

NOTES ON CARBOLIC ACID: APPLICATION OF PHENOL TESTS TO WORKS PRACTICE.

BY GEORGE H. SHARPLES.

PART I.

Some years ago it was noticed that there was always a serious variation between the quantities of phenol recovered from various oils and the theoretical valuation. These losses were important inasmuch as the quantity of recoverable phenol entered into the valuation of the oil when purchasing, and there was in consequence serious danger of commercial loss in working the oils.

Up to this time the valuation of tar acids had been carried out chiefly by Lowe's method and expressed in terms of 60's carbolite. As there seemed to be some doubt as to the precise constitution of 60's carbolite, this method was displaced in favour of the Weiss method for the determination of the phenol direct (first method, this Journal, 1913, 692).

The discrepancies continued, however, so it was decided to compare results obtained by the two methods in the same sample of tar acids, and

at the same time to examine the principles underlying each method. It was decided to adhere strictly to works conditions and use only such specimens as are produced daily in the works in the ordinary course of washing out the tar acids.

A series of samples was examined by both methods. In addition to the usual procedure in Lowe's method, a thermometer was placed in the retort with the bulb at the neck to note the range of the 625 grains collected and the specific gravity was taken. Each fraction obtained in the Weiss method was examined separately before mixing and where possible the quantity of phenol in the second fraction was determined. The sum of the quantities was taken and compared with the result obtained by mixing together the two fractions. The results (see Table I.) are stated with respect to the original samples.

This afterwards proved very useful in showing the relation of the specific gravity and the crystallising points to the amount of phenol in the presence of predominating quantities of mixed cresols, and the variation is no doubt largely due to *o*-cresol. In Weiss' method it will be known that the distillation is carried up to 170° C. At this point the flask is changed and the phenol separated from the water is added to the first fraction of the test. This small amount of phenol, as before stated, and confirmed by drying it carefully with concentrated sulphuric acid (cooled), contains considerable quantities of water, and as much as 2% of water might thus be added to the fractions under examination.

The effect of small quantities of water on the crystallising point and specific gravity was noted and the corresponding quantity of phenol determined.

Method of obtaining results:—

Column 4b: Calculated from Weiss' tables on the volume of crude acid, 5% being added for the first 10 c.c. distilled after driving off the water in accordance with Lunge's statement that this portion is 50% hydrated acid. (Coal Tar and Ammonia, p. 608, Vol. II., 4th Ed.).

Columns 5 and 6 range in which the 62.5% distils over (thermometer in vapour).

Columns 10, 14 and 17: Calculated upon original volume of crude acid.

In column 4a is inserted the % phenol obtained from a graph representing the value determined by a German firm according to

Lowe's method: this graph is made from several years' observations.

The oily matter was eliminated before the tests.

In Weiss' method it will be noted that in some instances it was not possible to determine the phenol in the second fraction alone, but phenol is adjudged to be present in small quantities as in every case but one the result of the combined fractions is greater than No. 1. fraction alone. The sum of the two fractions, however, where both could be determined, was greater than the single result on the combined fraction. In Lowe's method, column 4a represents the percentage of phenol from a graph based on observations of several years' use of this method by a German firm. The results compared with those obtained by Weiss' method, are widely divergent, being invariably higher.

Weiss' tables (Graph I.) were applied to the fraction of 625 grains in Lowe's method to determine if any relation between these two methods could be established, and 5% was added in accordance with Lunge's statement that the first 100 grains consists of 50% hydrated phenol. This result is only relative, as the range of the temperature, even in a retort, distilling direct, shows that considerable quantities of phenol must remain in the residues. This is confirmed by the difference between columns 4a and 4b. The results, however, are again widely divergent, and conclusions drawn therefrom as to the value of the tar acids must vary accordingly.

As Weiss' tables offered too much latitude in their use in determining the percentage of phenol from the crystallising point and the specific gravity, the graphs were rearranged as shown in Graph II.

% Water.	Sp. gr.	Cryst. pt.	% Phenol.
0.	1.0570	15.5	47.4
1.	1.0565	11.2	47.4
2.	1.0558	8.5	48.0
3.	1.0540	4.5	Out of range of table.

Weiss has modified his method since (this J., 1917, p. 863).

Table II. shows the effect on Lowe's tests caused by varying the amount of *m*- and *p*-cresol, and the water. There appears to be no rational conformity of results.

Lowe's tests.

PART II.

Lately (in January, 1916) it was found necessary in order to prevent loss of phenol in residues to adopt some ready means of determining small quantities of the former in crude cresylic acid. Lowe's test was not applicable, and our previous experience led us to seek other methods than Weiss'. It was necessary to adopt a quick method so that the plant was not held up whilst awaiting results. The Government shorter method was satisfactory when phenol was absent, but the difficulty was manifest when small quantities of phenol were present. The method described by Fox and Barker (this J., Aug. 15, 1917, p. 842) gave concordant and trustworthy results. The data given in that paper were accepted and the method applied directly to works' conditions and works' samples.

Sp gr. at 60°F.

GRAPH I.

It was found necessary to obtain pure samples of carbolic acid and distil cresylic acid until no phenol was present; *o*-cresol was then added to replace any lost in the extraction of phenol and to make such a mixture that more than 50% would distil over up to 195°C. In practice with cresylic acid containing low contents of phenol I have never found a mixture which would fulfil these conditions without the addition of *o*-cresol, so that 35 to 40% of *o*-cresol was always added at the commencement, dispensing with the preliminary distillation. Graph III. has been constructed with such a mixture, whilst Graph IV. was made without the addition of *o*-cresol.

Tests made with known mixtures on this method gave the following results:—

	Exp. 1.	Exp. 2.
Phenol in original mixture	19.4	15.0
Phenol estimated	19.2	15.9
<i>o</i> -Cresol present	64.6	57.0

The amount of *o*-cresol present in Experiment 1 approximates more closely to the constitution of the cresol used in Graph III.

The necessity for a graph made with a pre-determined mixture of cresols was amply demonstrated in the experiments made with other methods and other mixtures. In several instances negative results were obtained, that is, the quantity of phenol found was actually less than the phenol added. This was due entirely to the use of a graph made with the aid of a mixture of cresols not corresponding to the mixture under examination.

The method used by Masse and Leroux (this J., 1916, 1148), was examined in the course of the investigation but was soon abandoned for the above reason, coupled with the large quantity required for each test and the number of crystallisations required.

In this method the *o*-cresol is distilled off in the first portions, so that the latter portions contain only small quantities of phenol and are relatively weak in *o*-cresol. It is to these portions that the phenol must be added and the result is obtained from a graph which, in virtue of the presence of *o*-cresol, gives lower results from a corresponding crystallising point, hence a lowered value.

Again, the quantity of material taken affects the results, e.g., using a mixture of 70% of phenol and 30% of cresylic acid, 1501 grains gave a phenol content of 96% of that taken and 254 grains 90%. With smaller proportions of phenol the discrepancy was more marked.

In a mixture of 40% phenol and 60% *o*-cresol, over 100% of the added phenol was indicated by this method. In all the cases cited, Graph IV., which was made without the additional *o*-cresol, was used, giving higher results in the latter case, as the *o*-cresol was interpreted as phenol. In the former cases the opposite results were indicated. The Government method avoids this pitfall by determining the phenol always in a similar mixture.

The original Weiss method shows the same tendency to variation. The results are affected by the variation in the mixture of cresols used, a mixture with 30% *m*- and *p*-cresol alone, bringing the apparent percentage of phenol down to 70% and 60% *o*-cresol alone increasing the phenol to 125%.

In the application of these methods to practical work it is plainly seen that Masse and Leroux's method only furnishes a result which is a measure of the quantity of crystallisable phenol obtainable under ordinary working conditions, but the Government method gives a true index of the total phenol and bears no relation to the quantity obtainable. This was tested in the following experiment.

PART III.

Dark cresylic acid was distilled and concentrated in the laboratory so that the phenol could be extracted under conditions approximating to the ordinary working conditions. It was impossible, however, to reproduce those conditions exactly because within the works fresh material is constantly added and the concentration may be said to proceed in two directions: (1) → to phenol, (2) to cresol ←, the intermediate fraction containing proportions of phenol receiving additions in bulk which enable the distillation to proceed more freely.

In the laboratory, however, these fractions are constantly diminishing unless a large series of primary distillations are undertaken. The cresylic acid under examination was estimated to contain 4.09 % of phenol.

It is noteworthy that in section K, although a considerable quantity distilled below 194.5° C., viz., 50 c.c., no crystallisable phenol was obtained. This fraction proved to consist largely of *o*-cresol.

The bromine test as described by Fox and Barker was applied to the non-crystallisable fractions and showed the presence of phenol in slight quantities.

It has been found in making 60's carbolie by fractional washing that considerable losses occur, much phenol being left in the cresylic acid from the heavier oils, but if the whole of the tar acids are extracted without resorting to fractional washing and afterwards distilled much greater recovery of phenol can be effected.

That phenol is present in oil as heavy as creosote is well known, but by ordinary fractional washing it cannot wholly be recovered as the process would become tedious and involved, requiring

Phenol is here indicated in recoverable quantities in light creosote.

With reference to the bromine test used to ascertain the presence or absence of phenol in the residual fractions as indicated by Fox and Barker, trials were made to ascertain the limiting quantities of phenol which would be indicated. At first the indications appeared inconclusive, but with practice one was able to determine freely the presence or absence of phenol. Mixtures were made containing 10%, 5%, 2.5%, 1.25%, 1.0%, 0.66%, 0.5%, 0.2%, 0.1%, and 0.0% phenol. From these it was ascertained that 1.0% could be ascertained with certainty; below that point the results appeared doubtful.

many batches of graded weak carbolates to carry forward the phenol to the strong carbolate. The following tests show the presence of phenol, although Lowe's method gives no crystallising point

Liverpool Section.

Meeting held at the University, on Friday, February 15th, 1918.

MR. JOHN GRAY IN THE CHAIR.

THE MANUFACTURE OF TINPLATE.

BY T. LEWIS BAILEY, PH.D., F.I.C.

Tinplate consists of sheet iron, or more properly mild steel, which has been coated with a thin film of metallic tin, the main object of this being to protect the steel from oxidation (rusting) in a moist atmosphere.

One of the chief uses to which tinplate is put is for casing petroleum and some few years ago one-third of our export of tinplate went for this purpose; other extensive applications are for canning beef, fish, vegetables, fruit, etc., the manufacture of containing vessels for confectionery tobacco, and so on.

The production in this country runs into very high figures and entails the use of over a million tons of steel yearly and something like 16,000 tons of tin.

The tinning of iron sheets on any scale dates from the early part of the 17th century and

the early home of the industry appears to have been Saxony and Bohemia. In the latter part of the same century tinplate was made to some extent in England, though the industry did not flourish here until 1720, when works were established at Pontypool in Monmouthshire by Major John Hanbury; other works soon followed in the same county and the industry extended westward throughout the whole of South Wales. It is a curious fact that to-day this trade is almost confined to South Wales and Monmouthshire. The number of works in 1750 was four, in 1850 it had increased to 31, and 25 years later there were 75 works, since which date the actual number of works has not increased; present-day works, however, are on a much more extended scale, development in more recent times having been largely in the direction of increased output.

An excellently illustrated paper on modern tinplate manufacture was read by R. Beaumont Thomas in 1906 at a meeting of the Institution of Mechanical Engineers at Cardiff*, and a Home Office Report was published in 1912†, but textbook literature deals almost entirely with the older, now historical, methods, and a general summary may be found useful.

The earliest methods of making tinplate were described by Reaumur in 1725. Iron bars, about one inch square, were hammered out into thin sheets, which were cut to the requisite sizes by hand shears, then scrubbed with sandstone and pickled in water, rendered acid by means of fermenting barley meal. The pickled plates after being cleaned with sand and well washed were coated with tin. The pickling process occupied a couple of days and was carried out in vats, placed in vaults in which large fires were kept burning; periodically the workmen engaged on the operation entered the vaults in order to turn the sheets in the liquor to ensure even pickling.

The tinning of the sheets was carried out as follows: They were first immersed in molten palm oil, whence they were transferred vertically to a bath of molten tin; a thorough brushing of the sheets with a hempen brush followed this, and then came immersion in a second bath of tin, the molten tin in this case being covered with a layer of tallow. Excess of tin was removed by immersion in a bath of molten grease, after which the tinned sheets were cleaned and polished by hand with sawdust and moss. An excellent article was produced, with a heavier coating than is usual at the present time, when cost and competition are factors of such importance.

Present-day tinplate processes are of a totally different order.

The steel works deliver rolled bars, appropriately low in carbon (about 0.1%), to the tinplate manufacturer: these bars are from 6 to 10 inches in width and from $\frac{3}{8}$ to $\frac{1}{2}$ inch thick. The operations may be summarised as follows: details of general knowledge only may be given, of course.

(1) The bars are cut by means of bar-shears into desired lengths, usually about 20 inches.

(2) The cut bars are heated in the mill-furnaces and are rolled hot through two sets of rolls (roughing and finishing rolls). Sheet rolling was first introduced in 1728. According to present practice there are usually five separate heatings and rollings necessary to produce the requisite gauge of sheet.

After two heats the thickness of the sheets produced is under one-tenth of an inch; to ensure satisfactory rolling the sheets are doubled; doubling follows also the third heating and the fourth heating, so that after the fifth heating and rolling each sheet consists of eight layers.

By the employment of such methods a considerable output of thin sheet is attained in a short time. As an example of the results of rolling, a $\frac{1}{2}$ -inch bar will be transformed into a sheet of eight layers, each layer having a thickness of little over a hundredth of an inch.

Another method of rolling (so-called matching practice) common in America, consists in putting two pieces together after a first rolling; first doubling thus gives four layers and second doubling four layers.

Occasionally in matching practice three plates are used, in which case a first doubling gives six layers and the next twelve.

(3) The rolled "eights" are sheared by means of a plate shearing machine into three portions, which are trimmed, and thus from an original bar 20 in. \times 8 in. \times $\frac{1}{2}$ in. there will be produced, for example, 24 sheets, each 14 in. \times 20 in.

(4) Owing to the repeated heating, doubling, and rolling there is considerable adherence of the individual sheets and the operation known as "opening" is necessary; this is effected by starting separation at one corner and then tearing the sheets apart.

(5) So-called black pickling now follows, the sheets being immersed in dilute sulphuric acid, heated by steam. The object is to remove from the surface of the sheets the oxide scale, which has formed during repeated heating. In this operation the sheets are packed loosely into a carrier, which depends from one arm of the pickling machine. This is rotated to a point above the pickling vat, then lowered so that the sheets enter the acid, and an up-and-down motion is continued during the period of immersion. The pickling occupies a matter of a few minutes only and, when complete, raising of the carrier and further rotation takes the carrier with its load to a washing tank plentifully supplied with running water. At the same time a second arm of the machine has brought a fresh batch of sheets to the acid bath.

For pickling purposes hydrochloric acid took the place of barley meal in 1760, and this in turn began to give place to sulphuric acid in 1806. Sulphuric acid is now universally employed in the tinplate trade proper. Waste "pickle" still contains free sulphuric acid; after treatment with iron scrap, ferrous sulphate (copperas) is recovered by crystallisation.

Proposals have recently been made in the United States to pickle electrolytically*, the sheets forming the cathode in an acid solution.

(6) Annealing of the sheets is now necessary (black annealing). For this purpose the sheets are stacked horizontally on cast-steel or wrought-iron stands and covered with boxes of like material, sand luting being provided between cover and base. The annealing furnaces are either coal fired or gas fired and the operation occupies from 10 to 12 hours. The product is now what is generally known as "blackplate."

(7) Now comes a further rolling (cold rolling); the sheets are rapidly passed separately through three or sometimes four successive trains of rolls, whereby they attain considerable smoothness and polish.

(8) A second annealing (white annealing) follows, occupying about seven hours.

(9) A second pickling in sulphuric acid is necessary, but this is of short duration and after thorough washing in water the sheets are ready for to receive their coating of tin.

(10) Tinning. Hand labour is dispensed with as far as possible in all the operations hitherto described, and this applies also to the tinning operations; the old arduous methods have been superseded by the introduction gradually since 1866 of mechanical devices. The sheets are fed

* Proc. Inst. Mech. Eng., 1906, 499.

† Report on the Conditions of Employment in the Manufacture of Tinplates, with special reference to the Process of Tinning; by Edgar L. Collis and J. Hilditch. [Cd. 6394.]

* Thompson and Mahlman, this J., 1917, 1097.

by hand into the cast-iron tinning pot and are removed by hand ready for cleaning (though a device has even been introduced for transferring them mechanically from the tinning pot to the cleaning machines).

The tinning pots are of two varieties, a double horizontal type and a vertical type. In either case the sheets separately enter the tinning pot through a layer of zinc chloride solution, floating on the surface of the molten tin. The pots usually contain 3 or 4 tons of tin, kept molten by a coal fire under the pot. A succession of pairs of revolving rolls and guides at various positions guide the sheets on their way through the tin, downwards and then upwards until they emerge from the tin and pass vertically through a column of molten palm oil. During their passage through this latter a pair of rolls removes excess tin.

(11) The tinned sheets are now passed on to a cleaning machine, which carries them twice through a mass of bran or of "pink meal" (consisting largely of gypsum, mixed sometimes with sawdust) and this machine delivers them to a battery of dusting rolls covered with sheepskin, each alternate pair of rolls running at different speed to ensure polishing action on the surface of the now finished sheets.

The development of the tinplate trade has been essentially along mechanical lines but throughout the operations described there are problems which would well repay chemical investigation. At the end of the process, moreover, there exists a problem which is peculiarly chemical: it is that of the treatment of the dross, which collects on the surface of the tin in the tinning pot, a material technically known as tin scruff. This is periodically skimmed off and put on one side for treatment. It is a very complex mixture, containing 50% or even more, of metallic tin, mixed with chlorides of tin and zinc, iron and sulphur compounds and palm oil, together with oily decomposition products of palm oil. It is quite impossible satisfactorily to sample the material for sale to tin smelters and consequently it is heated in reverberatory furnaces at the tinplate works with production of a certain amount of metallic tin and a considerable oxidised residue containing tin, iron, and zinc, but now in a condition to admit of sampling for sale purposes. This operation, which should be a liquation process purely, is frequently carried out at abnormally high temperatures and causes the evolution of very dense fumes, containing considerable quantities of oxides and chlorides of tin and zinc, free hydrochloric acid, and products of destructive distillation of palm-oil. Such fumes, at one time evolved from short 20-ft. chimneys, were a source of trouble: they were very irritating and were, moreover, destructive of some types of vegetation in the neighbourhood of the works—the thick fumes travelled for considerable distances in the form of a thick white fog. Works dealing with the smelting or liquation of scruff were included as a class in the provisions of the Alkali, etc., Works Regulation Act, 1906, and investigations were carried out with a view to mitigating the nuisance due to the evolved fumes, and this resolved itself essentially into devising simple means for the reduction to satisfactory limits ($\frac{1}{2}$ grain per cubic foot) of the hydrochloric acid contained in the gases passing from the chimneys.* The problem of ascertaining the best possible method of treating tin scruff for the complete recovery of its valuable constituents could not receive attention, but it will be of interest to record some of the results obtained during the working out of the problem as it presented itself from an Alkali Act standpoint.

The method employed in "scruff-melting" usually consisted in charging a couple of hundred-weight or more of scruff on to the hearth of the heated furnace, allowing it to remain for a quarter of an hour until thoroughly heated to softening point, then stirring it, allowing it once more to remain dormant for a few minutes, then rabbling well for short spells during the remainder of the operation, until metallic tin practically ceased to run from the furnace. As it was usual to mix together all skimmings, those containing much zinc chloride and those containing little, it is evident that there were great possibilities of loss occurring mechanically and chemically during the furnacing operations: in most cases no dust-depositing flues were in use and the chimneys were very short; where flues of any length did exist they were frequently of small cross-section and led to a high boiler-chimney, not dampered off at the chimney end of the flue—a furnace damper only, naturally, had little effect on the deposition of fume in such flues.

The first modification introduced was to keep "flux skimmings" (*i.e.*, those especially rich in zinc chloride) separate from the scruff proper and to wash these thoroughly in running water heated by steam. This precaution had the effect of considerably reducing the amount of fume evolved and at the same time lower temperatures could be used for liquation and better yields obtained.

From many estimations made at different works, it was shown that, with flux skimmings present in the charge, the chlorides in the chimney gases were equivalent to 2 grains of hydrochloric acid per cubic foot, whereas when flux skimmings were kept out the chlorides in the chimney gases were reduced to less than 1 grain per cubic foot, in terms of hydrochloric acid: when flux skimmings were present in the charge 2½ grains of SnO_2 per cubic foot was present in the chimney gases, but if flux skimmings were kept separate, the escape of SnO_2 was less than $\frac{1}{4}$ grain per cubic foot.

The second step was the introduction of depositing flues for the purpose of retaining as much oxide of tin as possible, and at the end of the flues was built a simple type of wash-tower, in which hydrochloric acid was to be absorbed by water. All forms of tower packing proved impracticable: even pigeon-hole brickwork quickly became obstructed with thick greasy deposits that could not be removed by water. Towers with sloping shelves proved satisfactory from an absorption point of view, but breakages of the shelves were frequent, and ultimately unpacked brick towers were adopted, and to these water was supplied in the form of a shower from perforated plates, placed on the top of the towers. Two towers, each 9 feet high and 4 feet square, working in series, proved reasonably satisfactory for the purpose of removing hydrochloric acid from the gases. As a result of the various alterations adopted in the process the free hydrochloric acid was gradually reduced, after several years of patient work, from an average of 0.8 grain per cubic foot of chimney gases to 0.086, a figure well below the limit prescribed as the maximum permissible. The wash-towers have, moreover, had a further beneficial effect, in that they reduced the total acidity of the chimney gases (in terms of SO_3) from 1.55 grain per cubic foot to 0.48 grain. The extent to which it was possible to reduce the loss of oxide of tin depended chiefly on the depositing flues that were built: where reasonably large flues were put in, with a control damper at the chimney end of the flue, good recovery of flue dust rich in SnO_2 resulted, and this proved a valuable product, of course.

In 1915, at the desire of the Chief Inspector, special investigations were carried out on one plant, where a depositing flue and wash-towers had been installed. It was desired to ascertain the efficiency

* Annual Reports on Alkali, etc., Works, 1908 to 1913, the portions relating to Districts VI. and VII.

of both flue and wash-towers. Full details of the investigations, which extended over several days, are given in the Alkali Report for that year.* The depositing flue in the case in question was 125 feet in length and 2 feet square in section; the speed of the gases ascertained was from 4 to 5 feet per second (cold), furnace temperatures during the operation were 800° to 900° C., the mean temperature of the gases entering the flue was 440° C., ranging between 650° C. and 350° C., and this became reduced to 240° C. by the time the wash-tower was reached. The wash-tower contained two outer compartments, each 9 feet high and 4 feet square, and one intermediate compartment 9 feet high and 4 feet by 9 inches section, each compartment was provided with a water shower, the gases ascended in the two larger compartments and descended in the smaller intermediate compartment; the wash-tower cooled the gases from 240° C. to 105° C. Under such conditions 82% of the hydrochloric acid was removed and 42% of the oxide of tin leaving the furnace was condensed. The amount of tin passing away entirely from the system still constituted 10% of the total tin charged into the furnace. The furnacing operation includes long spells of rabbling of the charge and at such times there is admission of much air, so that an oxidising atmosphere prevails, by no means an ideal condition in a process of this kind. A furnace temperature of 900° C. must be considered high (considerably higher temperatures have been met with) and it was clearly indicated in the course of the investigations that with lower working temperatures there is improvement in the results, but the existing system itself might well be improved by the adoption of a larger condensing area, better regulation of draught, and by contact with water even in the earlier part of the system.

A method of scruff treatment that proved particularly suitable for small works consisted in washing the whole of the tin scruff for some days in water kept at somewhere near boiling point by means of steam, dissolved zinc chloride, etc., being continuously removed by a small continuous supply of water to the washing tank. The washed scruff lends itself to furnace treatment at a very low temperature, yields are good, and there is practically no evolution of either hydrochloric acid or tin compounds; depositing flues and wash-towers thus become unnecessary.

But of course there is in none of these methods any attempt at recovery of by-products with the exception of oxide of tin. What one would like to

see investigated is a self-contained method of complete scruff treatment on chemical lines, but, until some sort of chemical control obtains in the tinplate works, there is little likelihood of this and other problems being taken sufficiently seriously.

During the past few years three patents have been taken out in connection with the treatment of tin scruff. In 1909, H. J. Bailey* patented a combined smelting and lixiviating process and in the same year James Stephens† patented a separation and washing method, in which recovery of dissolved metallic compounds was aimed at. In 1912, S. B. Bowen‡ brought out an entirely different type of process: a preliminary heating of the scruff in a closed vessel by waste heat from the scruff furnace proper brought about liquation of a proportion of the metallic tin and at the same time chloride of tin and oily matter distilled and were condensed in small cooling towers; the liquated residue was then washed in water and furnace for further recovery of tin.

But progress has not been made on these lines; with lack of chemical control it can scarcely be looked for.

I desire to thank the Chief Inspector of Alkali, etc., Works for permission to give details regarding the work done in connection with scruff-furnace gases.

DISCUSSION.

Mr. JOHN GRAY hoped that chemists would find their way into this important industry in which there was obviously scope for them. Why was palm-oil used in preference to any other oil?

Dr. HORTON asked if there were any difficulties due to lack of uniformity in pickling and if so, what steps were taken to deal with them?

Mr. CARRUTHERS THOMSON wished to know the average percentage of tin in tinplate of modern manufacture. About 30 years ago he believed it had been of the order of 2½%.

Dr. BAILEY in reply said that tallow used to be used in the tin-pots but palm-oil was now used because it was eminently suited to the process and, moreover, was easily obtainable. In pickling, uniformity was ensured by insisting on a reliable acid (arsenic-free and of definite strength). At the present time tinplate contained about 1% of tin on the average.

THE ACIDIMETRY OF COLOURED SOLUTIONS: AN APPLICATION OF THE POCKET SPECTROSCOPE.

BY ALFRED TINGLE, PH.D.

(Preliminary Note.)

It became necessary at this laboratory to make acidimetric titrations of deeply coloured alkaloidal solutions, and it was found that the colouring matter could not be removed without vitiating the quantitative nature of the results. Ordinary methods of meeting the difficulty having failed, it has been found that the spectroscope offers a solution.

The absorption spectra of indicators are, of course, markedly different in acid and in alkaline solution, and the presence of an independent spectrum, arising from the natural colouring matter, does not prevent the observation of the first one, unless indeed it should happen that in some individual cases the two spectra overlap.

In practice the author has found it very nearly, if not quite, as accurate to determine the end point of an acidimetric titration spectroscopically as with the naked eye, and the spectroscopic method is certainly available in many cases where otherwise no end point could be seen. Obviously it can be used at night as easily as in day time.

The spectroscopic method.

Two similar vessels are provided, one of which holds the solution to be titrated, the other an equal volume of distilled water. To the latter is added one drop of the standard alkali to be used, and then an accurately-measured quantity of the indicator. The latter is added, a little at a time, till the characteristic absorption band shows a sharp enough edge. The quantity of indicator is noted and the position of the edge of the band is also noted. This position marks the end point.

The same volume of indicator solution is next added to the liquid to be titrated, after which titration is carried out in the ordinary way but for the fact that the spectroscope is used in place of the naked eye to watch the change of colour. In most cases this will be found to result from the shifting of an absorption band rather than the substitution of one band for another. The shifting may be gradual, but when the band watched has reached the position registered for it in the "blank experiment," the end point has been reached. In every case, it need hardly be said, the same thickness of liquid must be examined, but the shape of the vessel is of no importance. The author has often used a conical flask and obtained as good results as with any other container.

The spectroscope used in this work was a direct-vision Beck-Thorp diffraction instrument. It is one of the cheapest on the market and extremely convenient. A large spectroscope would be very unsuitable for such a purpose as the present one, but any handy instrument could be used. No

attempt has been made to express numerically the positions of the bands of the different indicators worked with. These vary with the dilution, thickness of layer examined, and perhaps other factors, and each worker must find those conditions best suited to his own peculiar eyesight.

In the following experiments the volume of liquid worked with was in each case about 60 or 70 c.c., and the thickness of layer examined about 45 mm. The solutions were contained in flat-sided tincture bottles. It will be noted that the volume of indicator used is much larger than would be suitable were observations being made with the naked eye.

Experimental results.—Every indicator hitherto worked with has been found to have its own peculiarities, which must be carefully studied before it can be used in connection with the spectroscope. Some of these are still being looked into and at present the author can only give details of methyl orange and cochineal.

A reliability test was made by measuring out definite quantities of decinormal sulphuric acid, colouring these with carefully neutralised extracts of black tea or stick liquorice, so that the end point would not be visible to the unaided eye, and then titrating by the method outlined above against decinormal soda.

Exp. No.	Vol. of $N/10$ H_2SO_4 by measurement. c.c.	Vol. of $N/10$ H_2SO_4 found by titration. c.c.	Indicator used.
1.	15.0	15.21	} cochineal 2.5 c.c.
2.	26.0	25.98	
3.	20.0	19.96	
4.	21.0	21.01	} methyl orange 1 c.c.
5.	17.5	17.49	
6.	14.0	14.11	
7.	18.5	19.16	

The failure in the last case quoted appears to have been due to a temporary defect in the source of light. This trouble was not suspected till the readings had been taken and the solution thrown away, so that re-titration was impossible. As a further factor in considering the degree of accuracy, it should be noted that while performing these titrations the author did not know what result he might expect, the acid having been measured by Mr. Babington, Chief Analyst to the Customs, the amounts not being disclosed till the titrations were completed. For this and much other help in other directions the author's best thanks are due to Mr. Babington. The cochineal solution used was a saturated extract made with 50% alcohol. The methyl orange solution was 0.1% of colouring matter in water.

Lately Mr. Babington and the author* commented on the different titre shown by solutions according to whether cochineal or methyl orange is used as indicator. The spectroscopic method appears to bring methyl orange back into line with cochineal and lacmoid. Figures cannot be quoted at present, but it is apparent that the spectra of neutral methyl orange and alkaline methyl orange are the same. From this it follows that the usual practice with this indicator of titrating to an intermediate tint is mistaken. Alkali should be added till the fullest change to yellow has taken place. Cochineal, on the other hand, changes colour as it becomes more alkaline.

The author hopes shortly to publish a more complete account of this work in connection with other indicators.

THE PRESERVATION OF BUILDING STONE.

BY CECIL H. DESCH, D.SC., PH.D.

(Abstract.)

The method of protection of building stone by means of soluble silicofluorides, first employed by Kessler*, is free from all the objectionable features possessed by the other methods which have been proposed or adopted for the purpose. The alkali salts are not used, on account of their sparing solubility, and also of the fact that, like the alkali silicates, they leave soluble carbonates in the pores of the stone as by-products of the reaction. On the other hand, the silicofluorides of magnesium, zinc, and aluminium, which are stable salts dissolving in water to form slightly acid solutions, yield only insoluble products with calcium carbonate. Carbon dioxide is freely evolved when the acid solution is applied to the surface of the stone, and the pores are closed by the formation of silica and insoluble fluorides. When the magnesium salt is used, the reaction is as follows:—

$\text{MgSiF}_6 + 2\text{CaCO}_3 = \text{SiO}_2 + \text{MgF}_2 + 2\text{CaF}_2 + 2\text{CO}_2$,
the protective layer being thus composed of silica and magnesium and calcium fluorides. I have found this method to be thoroughly effective in preserving even highly porous limestones against disintegration, and in reducing the porosity of those exposed to weather, as in the case of walls with a south-westerly aspect, through which the rain was able to penetrate freely before treatment.

A simple test of the porosity of a limestone may be made by using a flat sawn surface, and cementing on to this a short length of brass tube, 2 or 3 cm. in diameter, by means of a ring of molten paraffin wax. A measured quantity of water, say 5 c.c., is introduced into the tube by means of a pipette, and the time taken by the water to disappear completely is noted. A fresh area of the surface must of course be taken for each test.

Should the original limestone be of very open texture, it is advisable to prepare the surface by brushing with a cream made of dust of the same stone and water, allowing this to fill the pores before applying the silicofluoride solution. This assists in the formation of a compact layer, and does not alter the appearance of the stone.

Magnesium and zinc silicofluorides are crystalline substances, which dissolve without difficulty in water. The aluminium salt, which has certain advantages when used to treat highly porous limestones, does not crystallise well, and is usually replaced by the double salt of aluminium and zinc. All of these compounds are colourless, and as they yield only colourless products, the appearance of the stone is unaltered by the treatment. Copper and other coloured silicofluorides have been employed in the production of coloured surfaces on stone, but of the use of these materials I have no experience. The hardness of the limestone is increased considerably by the treatment, as is easily observed when the surface is scratched with a knife.

The silicofluorides, or "fluates," as they are called in commerce, have been manufactured at Clermont-Ferrand, where extensive deposits of fluor spar occur, and it does not appear that the industry has been established elsewhere. They

are transported in the solid state, and only dissolved when actually required for use. The method of protecting stone by this treatment is largely employed in France, but is rarely referred to in discussions on the subject in this country, which is my reason for communicating this short note to the Society.

DR. CHARLES A. KEANE IN THE CHAIR.

SOME COTTON SEED PRODUCTS IN THEIR RELATION TO PRESENT-DAY NEEDS.

BY ED. C. DE SEGUNDO, ASSOC. M.INST.C.E.,
M.I.MECH.E., M.I.E.E.

(Abstract.)

For many decades past, economists have drawn attention to the grave danger of our increasing dependence upon foreign countries for the necessities of life and for some of the raw materials indispensable to the welfare of our great staple industries. These economic problems have reached an acute stage as a direct consequence of the world-war, and we have good reason now to deplore the fact that we have to draw some 80% of our wheat supplies from overseas, and that only 20% of the cotton required for our spinning industry is obtained from regions within the British Empire.

The fact that Lancashire is dependent upon the United States crop for 80% of its cotton is serious enough, but the menace to the prosperity of our spinning industry is accentuated by the fact that within comparatively few years, the proportion of the American crop spun in American mills has risen from 36% to over 54%.

There can be no question as to the vital necessity of taking steps forthwith to increase the cultivation of cotton within the Empire; and as the production of cotton seed is an inevitable concomitant of the growing of cotton, it is of interest to draw attention to certain products obtainable from cotton seed—and particularly those of the woolly variety—which would serve:—

1. To provide a grade of edible oil admittedly superior to that obtained by the method now practised in Great Britain in crushing cotton seed, and admittedly unrivalled for the manufacture of margarine and artificial lard;

2. To provide a flour, containing over five times the protein and fat content of wheat flour, the employment of which would enable us to reduce our wheat imports; and

3. By turning to account the short cotton fibres remaining upon the shell of the woolly cotton seeds, to provide a supply of raw material for the manufacture of explosives, paper, etc.

Probably upwards of 95% of the cotton grown in the world is of the "Upland" or "woolly" variety, frequently referred to as "rain-grown" because it is cultivated under ordinary climatic conditions, *i.e.*, without recourse to irrigation. This seed is covered with an under-growth of "fuzz" or short cotton fibre in addition to the long staple cotton.

Under certain conditions, naturally obtaining or artificially produced, a variety of cotton is grown, which, upon being ginned, leaves the seed "bald" or "black." Practically all the cotton is of long staple and removable in the ginning process. The quantity of such cotton grown

* L. Kessler, *Comptes rendus*, 1883, 96, 1317. Faure and Kessler, *Eng. Pat.* 4954 of 1883; this J., 1884, 414.

is very small compared to the world's crop of some 21,000,000 bales. The greater portion of such seed comes from Egypt. A very small quantity is grown in the United States.

American and British systems of crushing cotton seed.

(a) *British practice.* According to the British practice, the cotton seed—whether it be of the bald or of the woolly variety—is crushed whole just as it is received. The oil is consequently impregnated with the tarry compounds and deep colouring matter contained in the shell, and in spite of recent advances in the processes of refining and deodorisation it is difficult to remove these impurities; indeed some authorities state that they can never wholly be got rid of.

The residue after expression of the oil, consists of the kernel-remains, the shell, the "fuzz," and a certain amount of dirt and foreign matter, forming a cake containing about $4\frac{1}{2}\%$ to 5% of oil and used only as a food for adult cattle. The presence of the "fuzz" detracts, moreover, not only from the appearance, but from the food value of the cake.

In pre-war times, Egyptian seed fetched from £2 to £3 more per ton than the woolly varieties, and the cake made from Egyptian seed sold at 20s. to 30s. more per ton than that made by the British method from woolly seed.

(b) *American practice.* The system adopted practically throughout the United States is that known as the "decorticating system." The cotton seed is run through a "huller" the function of which is to split open the shell of the seed and free the kernel. The mass of broken shell ("hulls") and kernels ("meats") issues from the "huller" and falls upon a shaking sieve, through the meshes of which the meats can pass easily. The hulls matt together by reason of the fuzz upon them, pass over the shaking sieve, and are carried away to a suitable store.

Since the fuzz absorbs oil very readily from the naked kernels in the hulling machine during decortication, it is customary in American practice first to remove a portion of the short cotton fibre in a linting machine. If too much of the fibre be removed, however, pieces of the hull will be more liable to fall through the shaking sieve together with the meats. In first-class practice (in pre-war times) an efficiency of separation of the meats from the hulls of 98% and even of 99% has been claimed with up-to-date decorticating machinery.

The residue of the meats after expression of the oil is called "decorticated cotton seed cake" and is sold as such or is ground to a meal, when it is known as "cotton seed meal." From this meal the cotton seed flour for human consumption is prepared.

During the early years of the development of the industry in the United States, the "hulls" were looked upon as a waste product and were frequently used as a fuel but more often burnt to dispose of them. Subsequently it was found that they could be used as a roughener in the manufacture of feed for cattle—indeed, large quantities of hulls have been fed direct to cattle.

Of recent years, means have been devised for the mechanical separation of the hulls into their component parts of cotton fibre and shell-bran, the former being employed for the manufacture of explosives, paper, artificial silk, cellulose acetate, and other cellulose derivatives, and the latter as a basis for the production of various forms of mixed feeds for cattle.

When the process of decortication is efficiently carried out and a practically complete segregation of the meats (kernels) achieved, the oil expressed is very pure and easily refined, the loss on refining being from 5% to 9%. On the British system, this loss may be taken as from 11% to 15%, and,

in some varieties of Indian seed, the loss is stated to be from 16% to 20% and even higher.

Twenty years ago the decorticated cake made in the United States contained as much as 10% of oil. In good (pre-war) American practice it was between 6% and 7%. Since the war broke out, American oil millers have succeeded in further reducing the percentage and to-day some mills turn out cake containing little more than 5%.

In first-class British practice, the percentage of oil in undecorticated cake is from 4.5% to 5%. The percentage of decorticated cake made (calculated upon the weight of the seed as received by the mill) is from 40% to 45%, depending upon the degree to which the seed is linted before decortication. The weight of undecorticated cake, on the British system, is 85% or more.

From these figures it will be seen that as the ratio of the weight of undecorticated cake to decorticated cake is greater than the ratio of the percentage of oil left in the decorticated cake to that left in the undecorticated cake, the percentage of oil expressible, on the weight of seed, by decorticating must be higher than that obtainable by crushing the seed whole (British system)—subject to a small correction for oil left in hulls. The following figures will serve to illustrate this point:—The average production of cake and hulls in the United States expressed as a percentage of the weight of the seed crushed, was 43.7% cake and 33% hulls for the years 1910-11, 1911-12, 1912-13 (calculated from the returns of the United States Census Bureau). Taking the percentage of oil left in decorticated cake as 6%, that in the hulls as 0.7% (average for seven years), that in undecorticated cake as 4.75%, and taking the total oil content in average Upland American seed as 18%, the oil expressed from 100 tons of such seed efficiently decorticated would be 15.15 tons. If these hundred tons had been crushed on the British system, it may be calculated that the amount of oil expressed would have been 13.9 tons, or 1.25% less than with efficient decortication.

The presence of shell in the undecorticated cake imparts astringent and other properties to the cake which are not without certain advantages, particularly in the feeding of milch cows at certain times of the year, but this circumstance can, at best, only be urged in extenuation of the British system, not in praise of it. On the improved American system, the defibrated hulls are recovered as a separate product and can, together with other suitable ingredients, be compounded with the kernel-remains of cotton or other seed to produce a balanced ration. The "compounding" of the kernel-remains with the shell and other substances entails of course some additional expense, but apart from the better price such "balanced feed" should command, the cost of grinding and mixing should be more than off-set by the profit on the short cotton fibres recovered from the decorticated hulls of woolly seed, not to speak of the increased value as a roughener.

Edible oil for the manufacture of margarine.

Cotton seed oil obtained by the American method, i.e., expressed from the kernels alone, is unrivalled for the production of the highest qualities of margarine and the oil is easily refined with a smaller loss and at a lower cost than that expressed by crushing the seed whole as on the British system.

Cotton seed flour as food.

The credit for the introduction of cotton seed flour as an article of food for human consumption is due entirely to the late Colonel J. W. Allison, one of the pioneers of the cotton seed oil industry in the United States. He first directed attention to the possibilities of decorticated cotton seed meal as a food for human beings in 1876. He stated

recently that cotton seed flour is twenty-five times as nutritious as potatoes, five times as nutritious as corn (maize) meal, and four times as nutritious as oatmeal.

Choice cotton seed meal must contain (according to the rules adopted by the Memphis Merchants' Exchange) not less than 49% of combined protein and fat. The average analysis (before the war) is given as 45% crude protein and 6% fat. Owing to the rough and ready manner in which the cake is handled in the mill, impurities and foreign matter are liable to be introduced, and the meal ground therefrom must therefore undergo certain purifying processes in its conversion into cotton seed flour for human food.

The serious attention of the United States Government is being given to the utilisation of cotton seed flour as a means of mitigating, in some measure, the deficiency in the supply of wheat flour and also as affording, in some measure, a substitute for meat.

The composition of cotton seed flour will naturally depend upon that of the meal from which it is produced. Some samples contain as much as 66.64% of crude protein and fat (of which 10% is said to be fat). G. S. Fraps gives the composition as 51.19% crude protein, 11.40% fat, 22.22% nitrogen-free extract (carbohydrates), 3.05% crude fibre, 7.21% water, and 6.0% ash. It is stated that the nitrogen-free extract of cotton seed meal is composed most largely of raffinose and that it contains no starch.

Messrs. Cross and Bevan give the following analysis of imported cotton seed flour:—Albuminoids (N x 6.25) 50.40%, oil and fat 8.77%, digestive carbohydrates 22.79%, crude fibre 4.50%, moisture 8.32%, ash (mineral matter) 5.16%. They report that the sample may be described as a starch-free seed-flour.

It may be said that cotton seed flour contains no starch, about 54% crude protein, and from 7 to 10% of fat, while wheat flour contains a high percentage of starch, from 10 to 12% crude protein, and from 1½ to 2% fat. The coefficient of digestibility of the protein in cotton seed flour is given as about 88% and that of the protein in wheat as about 94%. On the other hand, the digestibility of the fat in the cotton seed flour is about 93% as compared with 90% for the fat contained in wheat flour.

The protein and fat content of cotton seed flour is about 5 times that of wheat flour. It cannot therefore be substituted entirely for wheat flour in making bread (except perhaps under medical advice in cases where a starch-free diet is necessary), but it is eminently adapted for use as a diluent for wheat flour up to one-fourth or one-third of the wheat flour. Trial bakings made in London with various mixtures of cotton seed flour, potato flour, and wheat flour indicated that the best all-round proportions were about 25% of cotton seed flour, about 69% of wheat flour, and about 6% of potato flour (percentages calculated on solids only). Taking the moisture in these loaves at 25%, the crude protein content would be about 16.9% by weight, which is about twice that in an all-wheat loaf, and, indeed, approximates to that of high quality lean meat.

A great number of experiments on feeding cotton seed meal to animals have been made and it is well known that cattle thrive upon a properly balanced cotton seed meal ration. Experiments on the dietetic value of cotton seed flour for human beings have not been carried out for long enough periods of time to enable final conclusions to be drawn, but so far as such experiments have gone, there would seem to be no objection whatever to cotton seed flour as a food for human beings, provided it be intelligently administered.

According to an American authority (Dr. de Loach) it would be safe to supply 20% of the

protein we daily consume (or should consume) from cotton seed flour. A mixture of 5% cotton seed flour, 10% potato flour, and 85% wheat flour (percentages calculated on the weight of solids only) would yield about 9% protein on the total weight of the bread, including water.

To produce 350,000 tons of cotton seed flour (which is 5% of our annual consumption of 7,000,000 tons of wheat flour) would require the decortication of about 1,200,000 tons of cotton seed. Bearing in mind that the kernel occupies about 50% of the volume of the whole seed, our British cotton seed oil mills, which now crush upwards of 500,000 tons of cotton seed per annum, would, by suitably modifying their press boxes, be able to deal with 1,200,000 tons per annum (if the decorticating system were employed) without interfering with the treatment of the other oil-bearing seeds now crushed.

With the production of 350,000 tons of cotton seed flour from Upland seed by the decorticating system, there would be produced about 170,000 tons of refined cotton seed oil suitable for the best grades of margarine, about 2,500,000 bales of cotton for spinning, about 60,000 bales of high grade lint, and about 250,000 bales of hull fibre and seed lint. The Anglo-Egyptian Sudan would be suitable for the growth of the necessary cotton seed for these products, but it must be borne in mind that the cost of putting the 2,500,000 acres that would be necessary under cotton alone would involve large sums of money, and that the labour required could only be supplied by a population many times greater than that of the Anglo-Egyptian Sudan to-day.

The admixture of 5% cotton seed flour and 10% potato flour with the wheat flour employed in making our bread would reduce our wheat imports by about 1,050,000 tons, or by nearly 20%.

Utilisation of the short cotton seed fibres on the woolly varieties of cotton seed.

Until recently, these short fibres were entirely neglected, but they are now successfully separated from the hulls by a mechanical process. The short fibres (or hull fibres) have already been employed in very large quantities by the Du Pont de Nemours Powder Company in America, for the manufacture of explosives, and before the outbreak of war, increasing quantities were being annually employed by papermakers in Great Britain and in France in substitution for rags and textile wastes for the manufacture of the higher grade qualities of paper.

Quite recently another machine has been introduced which, it is claimed, will detach the shorter fibres from woolly seed that has already been lightly linted and deliver the fibre in so clean a state that the yield of cellulose obtained therefrom approximates to that of raw long cotton.

It may be asked why the American system has not been adopted in Great Britain. One answer to this question is given in the recently published Bulletin of the Imperial Institute (No. 3 of Vol. XV., July—Sept., 1917) in the following words:—“The reason of the backward condition of the oil and seed crushing industry (in Great Britain), taken as a whole, is mainly that it began in the days when oil-cake for feeding cattle was the chief desideratum and the oil a relatively unimportant material, and this has largely determined the kind of seeds crushed.”

It is certainly the fact that, speaking generally, British crushers have devoted their attention in the past chiefly to oil seeds giving a comparatively low yield of oil and a high yield of cake. One obstacle to the adoption of the American system by British seed crushers is to be sought in the difficulties attending any attempt to introduce products differing in appearance or character from

those for which the demand has been long established. On the other hand it appears that the technical questions involved in modifying the oil mill equipment do not present any serious difficulties, nor would the capital outlay on such modifications constitute a matter of governing importance.

In recent years, and in particular since the outbreak of war, the whole situation has been greatly changed. The demand for oils for the manufacture of margarine and other edible fats which sprang up some ten years or so ago on the Continent, was not at first reflected in this country. The German seed crushing industry, being of comparatively recent origin, commenced with the advantage of up-to-date equipment. Special attention was paid to copra, palm kernels, ground nuts, and other seeds having a high oil content, and in the result, German seed crushers "have not only monopolised to a large extent the crushing of rich oil seeds but have also made inroads into the crushing of cotton seed which, so far as Europe is concerned, had been until the last few years (before the war) practically a British monopoly."

The extent of these inroads may be gathered from the fact that, in 1905, 94.4% of the exported Egyptian crop came to British mills and in 1913 the proportion had sunk to 51.6%, the remainder going practically entirely to Germany.

At first sight, it would seem that the era of working cotton seed is drawing to a close. This is, however, not necessarily the case. Let it be conceded that, in the future, oil will be the primary and cake the secondary consideration, and that the richer oil-bearing seeds will come more and more into demand, the fact remains that we must have cotton.

The greater the preferential demand for the richer oil seeds, the more will cotton seed tend to become a drug in the market—at least in the export market. Nevertheless, the intrinsic value of the high grade oil and of the protein and fat content of the decorticated cake, will remain unaltered, and the rise into favour of the richer oil seeds should therefore operate to stimulate activity in the crushing of cotton seed in the countries of origin. The pure oil will always hold its market and the cotton seed cake or meal, or the cotton seed flour obtainable from the pure kernels, should always command a market at a price based upon its high protein and fat content. In view of the fact that the recovery of the short cotton fibre, before and after decortication of the seed, is now a commercially established industry, there is no longer any reason why the crusher should hesitate to leave enough "fuzz" on the woolly seeds to ensure high efficiency in decortication and thus to produce the highest grade of oil and cake.

One mill in this country, at least, has under serious consideration the erection of a decortivating plant with a view to the adoption of this system on a large scale upon the conclusion of the war, when supplies of woolly seed may be expected to become available in even larger quantities than hitherto.

For reasons arising partly out of the increase in the home consumption of cotton in the United States, it is probable that after the conclusion of the war, Great Britain will have to provide a means of crushing very much larger quantities of the woolly varieties of cotton seed than have hitherto been dealt with. Thus, the question of the relative merits of the British and the American methods is likely to become an increasingly important one.

The decortivating system, plus the plant for defibrating the seed (before decortication) and the hulls (after decortication) involves a larger capital outlay per ton of seed treated than the British system. On the other hand, the profit realisable from the treatment of woolly cotton

seeds by efficient decortication in combination with judicious linting and defibration of the seed, and defibration of the decorticated hulls, is appreciably higher than that realisable for the products arising from crushing the seed whole, after deduction of the milling costs involved in each system.

In dealing with woolly seed, there can be little question as to the method of milling which should be adopted.

It is clear that, did a decortivating system exist whereby the meats of bald seed could be segregated efficiently from the hull (or shell of the seed) such seed could be turned to more profitable account in that way than by crushing it whole.

Logically, the grading and selection of the seed for planting, the growing and picking of the cotton, the ginning of the seed-cotton, the baling and pressing of the fibre, the linting and defibrating of the seed, the decortication of the seed, the production of oil and cake, the defibration of the decorticated hulls, and the utilisation of the shell-bran should, as far as practicable, be carried out under the control of one organisation in the country in which cotton is grown. Only those practically concerned with cotton cultivation realise what an immense difference it would make if proper attention were paid to the selection of seed and if the production of seed and the milling thereof were in the same hands. Incalculable advantage would also be gained by the country itself, as only such proportion of the products would be exported as were not consumed in the country, the manurial value of the cake fed to cattle alone being an important item from the agricultural standpoint. Having regard to the enormous areas throughout the Empire where climatic conditions favour the cultivation of cotton, there should be room for many such organisations, and opportunities would be afforded for the remunerative employment of practically unlimited capital.

DISCUSSION.

DR. BERNARD DYER doubted whether the author was right in attributing the dark colour of the oil obtained from the English crushing method to the presence of the husk of the seed. In a cotton seed there were a number of crimson spots which indicated colouring matter. In the laboratory dark red oil was obtained from decorticated seed. He did not know that it would altogether be to the advantage of the farmer if Egyptian seed were decorticated before it was crushed. The very presence of the husks gave a special value to the cake; it gave an astringent properly which was very valuable to cattle feeding on grass at the full height of growth, and the farmer valued it very much for that reason. When the woolly Bombay seed was here crushed whole, it was anticipated that it would be injuriously indigestible, but experience had shown that cattle did as well on it as on Egyptian seed cake, allowing for the slightly less value. It was more than 40 years ago that he first became familiar with decorticated cake when he was working under the late Dr. Voelcker. This cake contained sometimes as much as 50% of albuminoids; if the seed was squeezed sufficiently the oil might be 10%, but was usually from 12 to 15%. That most valuable cake, however, had for a number of years ceased to appear in England, but instead there were enormous quantities of American so-called decorticated cotton seed meal. It was an extraordinary thing that really decorticated cake did not come here if the old process was still worked. The meal now sent usually contained something like from 33 to 37% of albuminoids, and though it was excellent food he thought it should be called "partially decorticated" cotton seed meal. He had been assured that the large proportion of hulls in this meal was not due to the re-admixture of

hulls with the decorticated cake but was due entirely to the fact that owing to the better process of de-linting they were no longer able to decorticate the seed properly. He had supposed that the fraction which was called the "bran" was mixed with the seed, but he had been assured that that was not the case. Could the author tell them what really was the case? Was the process carried out as he had described or was it only occasionally carried out for special purposes in its original form?

Mr. ERWIN W. THOMPSON, after outlining the methods of decortication and of the extraction of the oil from cotton seed in use in the United States, said that progress in the art of milling, looking towards a greater yield of oil, as well as changes in the relative market values of the products, had brought about many changes in the character of the products. At first efforts were made to produce pure cake entirely freed from the hulls. In sifting the cut seeds with this end in view, much of the kernel was inevitably carried away with the hulls. As manufacturing profits began to diminish, it became necessary to conserve these wasted kernels, but in sifting for this latter result much of the hulls would inevitably be run in with the kernels. Thus the resulting cake would contain less nitrogen than formerly. Just before the war, average merchantable American cake would contain about 40% crude protein and 7% fat, compared with 50% and 12% in the "pure" cake as at first made. Since the beginning of the war, cake had degenerated still further, say to 30% and 5%, thus approaching the composition of the Egyptian cake made in England. This condition had been indirectly brought about by the war demand for cellulose and raw materials from which to make it. A certain amount of fuzz or short lint left on the hull was a *sine qua non* for good decortication by the American system. Now, in the effort to produce the greatest amount of fibre to meet the war demand, the seeds were being more closely defibrated before cutting, and hence the smooth hulls passed through the sieve along with the kernels. Meanwhile the quality of the oil pressed from these hully kernels was also depreciated, but the demand for fats of all kinds kept the price high and the buyer uncritical. After the war there would probably be a reaction in the United States toward cleaner decortication; but if the demand for fibre continued, as it probably would, the mills would have to meet the situation in one of two ways, *v. z.* :—

(1) By the invention of some new way of decortication for the separation of denuded shells from kernels, or (2) the division of the production of fibre into two operations, first the removal of only a portion from the seed before cutting (leaving enough fibre to ensure perfect decortication according to the old method) and then removing the rest from the hulls after they had been separated from the kernels. If the demand for cottonseed flour should rapidly develop for ameliorating the wheat shortage, the return to better decortication would probably begin very soon in the United States, because good flour could not well be made from seed worked whole. Cottonseed flour could be made from the woolly seed which constituted about half of the British crush of cottonseed, by installing standard American machinery and methods of decortication, and by altering the boxes in their hydraulic presses, but for the bald Egyptian seed some new method would have to be invented to separate the kernel from the shell or hull. No such method had heretofore been installed because the demand for decorticated cakes in England had not been important. In fact some British millers went so far as to say that the British cattle feeders actually preferred undecorticated cake. That, however, was an artificial and unscientific con-

dition and did not exist to any extent outside of the British Isles. The demand for undecorticated cake had grown up, not because of its excellence, but because of the large home supply. New conditions which were now developing in England in the supply of oil cakes would eventually develop a new demand. Pressing palm kernels was one of the industries which England had taken away from Germany, which formerly had a practical monopoly of it. Copra, soya beans, and peanuts were also being pressed in England in greater quantities than heretofore. Cakes made from all these new materials must be sold and fed just as they had always been to such great advantage in Germany. Undecorticated cakes made in Germany were not fed there but exported to England. Soya and peanut cake had about the same composition as decorticated cottonseed cake, so that a demand once established for any one of these cakes would be easily satisfied with either of the others. But whether Egyptian seed were ever decorticated in England or not, it was quite probable that woolly seed would be, particularly if there were to be an augmented supply of these products from Uganda, Nigeria, and the Sudan.

Mr. E. T. BREWIS asked what was the percentage of oil in the kernels, as distinct from the total oil contained in the seed, and also what was the minimum amount of oil that could commercially be left in the cake.

Capt. C. J. GOODWIN asked for more information as to the manufacture of artificial silk. How did the raw material compare as regards cost and yields with the materials usually employed, and what process had been found most suitable for its manufacture from the cotton seed fibres? With regard to the amount of oil left in the cake referred to by Mr. Brewis, this was from 5 to 7% in the American system and from $4\frac{1}{2}$ to 5% in the case of the British system. Was it intentional that there was more oil left in the American cake or was it due to bad crushing?

Dr. R. SELIGMAN asked if the figures given for the loss in refining were strictly comparable, *i. e.*, whether they were records for the same year and for the same season of the year; also to what extent the refining was taken in each case, whether to the "soap oil standard" or to the "finely deodorised edible oil standard."

Mr. P. J. NEATE asked as to the possibility of installing decortication plant where the seed was grown, dealing with it on the spot and then importing the kernels instead of the seed. He also endorsed the possibility of winnowing the seed instead of sifting it.

Mr. E. C. DESEGUNDO, replying to the discussion, said that the reason that the decorticated cake was now different from formerly was not because the decortication system, *qua* system, had been interfered with, but because so much of the short fibre was now being taken off the seed, especially since the war started. The shell was thus so denuded of fibre that the pieces could not lap together and a portion of the shell fell through with the seed and became crushed with the cake. He granted that the shell gave an astringent quality to the cake but that fact could only be urged in extenuation of the British system and not in praise of it. The seeds could very well be decorticated and then some of the shells mixed with the cake in any proportion desired. As to the kind of oil and the standard of refining, the figures were fairly comparable so far as he was aware. Twenty years ago decorticated cake contained from 10 to 11% of oil. The American oil miller prided himself in those days on the efficiency of decortication and often got as much as 98% of kernels. His statement that cottonseed flour had five times the value of wheat was based on the fact that it contained from 60 to 66% of crude protein against 12% in wheat. He agreed that

there was no starch in cotton seed and that there was in wheat, but in the comparison in the paper that had been taken into account as the calculation was made in calories. The object of the paper was to indicate that if the 600,000 tons of cotton seed that was crushed in this country to-day were decorticated, there would at least be some additional flour. The percentage of oil in cotton seed varied from crop to crop, and it was only possible to work on rough averages. He had known it vary from 18 or 19% to from 30 to 35%. In the naked kernels it had been as high as 38%. The minimum that could be left in the cake was about 5%; he did not think it could be got lower. That made a very hard cake. He had been told that on the British system, using Bombay cake, it had been brought down to 3½%. With regard to artificial silk, within the last two years there had been great conflict of opinion among experts as to whether better results were obtained with wood cellulose or cotton cellulose, but it had recently been definitely decided that cotton cellulose gave the best results as regards lasting qualities and water-proofing. He did not think it would be practicable to import the kernels instead of the seed as the kernels would soon decompose on the voyage.

Meeting held at Bolbec Hall on Wednesday, March 20th, 1918.

MR. H. PEILE IN THE CHAIR.

THE DELETERIOUS EFFECT OF USING SALINE OIL COKE IN THE MANUFACTURE OF CARBON ELECTRODES.

BY H. SCRAGG.

The object of this note is to show the adverse influence of the presence of salt in the manufacture of amorphous carbon electrodes where high density and purity are the essential features aimed at. The saline oil coke is chiefly derived from Russia, presumably from around the Black Sea, and contains from 6 to 7% of sodium chloride. Scottish oil coke, however, is free from such impurity and gives rise to no trouble. The following is an analysis of saline oil coke:—Moisture, 2.89%; volatile matter, 4.65%; insoluble ash, 0.80%; sodium chloride, 6.40%; and carbon (by diff.), 85.26%. It is obvious from the analysis that the sodium chloride can very readily be washed out by suitable means with hot water, and it is possible that, during calcination, a loss of sodium chloride would occur. That, however, is based on the supposition that the temperature attained in a furnace would be as high as usual, but it has been found that the presence of sodium chloride seems to prevent such a high temperature being attained as with saline-free oil coke, when the temperature would be as high as from 1400° to 1500° C., the lowest being from 1100° to 1200° C. The highest temperature recorded when calcining saline oil coke was 1100° C., whilst, in parts, it was as low as 880° C. That circumstance has an important bearing on the question, as the volatile sodium chloride would not be expelled but would merely pass from one portion of the furnace to another, finally condensing on the cooler coke at the top or dropping back into the furnace when the lower portion is withdrawn. Instead of a loss of sodium chloride, a process of concentration would go on until the furnace was finally drawn. Moreover, the density of the oil coke is not all that could be desired. In practice, it has been found that the sodium chloride increased from 6% in the original to 8%

in the calcined coke and, at the same time, the insoluble ash rose from 0.80% to 1.2%. The latter was very probably due to the action of fused chloride upon the furnace lining. It would, indeed, be very bad policy to attempt to make electrodes from the calcined material and, apart from washing out the soluble chloride, the only alternative would be to dilute the coke with other oil cokes free from salt, thereby obtaining a mixture containing, say, 2% NaCl. There, again, on mixing the ground coke containing from 1 to 2% NaCl with suitable binding material and pressing the whole into block form and baking, a further set-back is experienced. The density of a finished electrode should be at least 2.00, that is if it is to be at all durable; it would seem that, in the case of electrodes containing salt, the density falls with increasing percentage of that impurity. Thus, with oil coke containing 1.51% of NaCl, the density was 1.95; with 1.63%, 1.92; and with 1.78%, 1.89; whilst another block, baked at the same time but free from salt, had a density of 2.00. The presence of sodium chloride only would tend to make the density more than normal, supposing, of course, that the remainder of the block attained a density of 2.00, so that it is quite evident that the low density must be accounted for in other ways, e.g., low temperature of calcining with saline oil coke, improper baking temperature, or the sodium chloride in the block preventing the escape of volatile matter. In one case an electrode free from chlorides, when baked alongside of some containing salt, attained a density of 2.00. Many of the electrodes when finished are found to be blistered and to have whitish marks on the face; these blisters point to the volatile matter being unable to escape.

DISCUSSION.

The CHAIRMAN said he did not know whether the presence of salt in an electrode would have a bad effect in a steel furnace. It was difficult to say to what the bad effect was really due.

Dr. J. T. DUNN thought that it would have been possible to wash out the salt.

The CHAIRMAN explained that all the best oil coke at present was being used in aluminium manufacture. The oil coke used in the manufacture of electrodes was mixed with other ingredients, such as gas carbon and anthracite, the result of which was to give a better product than was procurable from any one sort of carbon.

Mr. F. CAMPBELL remarked that, with reference to steel furnaces, he thought the only trouble would be that salt would damage the bricks and make them "run." It would not interfere with the steel; in any case it would be volatilised before it got into the steel. One of the troubles in making aluminium was that, if the furnace got too hot, there was much more sodium formed.

Mr. W. JONES said that some Scottish coke he had examined recently contained from 3 to 4% of sodium sulphate. Very often it contained as much as 5%.

The CHAIRMAN said that the best cokes made in Scotland were free from salt, but some of the other Scottish cokes contained it.

Communication.

ON THE QUALITY OF GLYCERIN FROM WHALE OIL.

PART I.—AN EXAMINATION OF THE IMPURITIES IN GLYCERIN FROM WHALE OIL WITH REFERENCE TO THE SUITABILITY OF SUCH GLYCERIN FOR THE PRODUCTION OF DYNAMITE.

BY A. H. SALWAY, D.S.C., PH.D.

It is well known that, in recent times, the supply of oils and fats has been so regulated that

the best vegetable oils are reserved for the manufacture of butter substitutes, whilst non-edible oils, including fish oils, are utilised for the manufacture of glycerin and in other industries. In consequence of this system of control, whale oil is now being used to a much larger extent than heretofore in the production of glycerin for explosives. From time to time, however, doubts have been expressed regarding the suitability of whale oil for this purpose, chiefly on account of the possibility of impurities from the oil passing into the glycerin and rendering the subsequent nitration process dangerous. It seemed, therefore, desirable, as suggested by the Ministry of Munitions, that an investigation of the subject should be made with the object of determining the amount and the nature of the impurities in glycerin from whale oil, and also for the purpose of deciding whether such glycerin can be safely employed for the manufacture of dynamite. In accordance with this suggestion, the investigation recorded in this paper was undertaken.

1. The examination of whale oil glycerin for the presence of trimethyleneglycol.

Since whale oil of poor quality is liable to undergo fermentative changes with the possible production of trimethyleneglycol, it was decided to examine a number of crude glycerins from whale oil for the presence of this compound. Accordingly a number of whale oils of different quality (No. 0 to No. 4 quality) were procured. These oils were severally hydrolysed in 100-lb. batches, some by the autoclave method, others by the Twitchell process, and others by alkaline saponification. The aqueous glycerins so obtained were purified by the methods usually adopted in the respective processes of hydrolysis, and then concentrated to a strength of about 80% glycerin. For the estimation of trimethyleneglycol in the crude glycerins, the latter were distilled under diminished pressure, and the specific gravity and apparent glycerol content (acetic method) of the distillate determined. From these figures a sufficiently accurate estimation of the trimethyleneglycol content can be made, assuming that the only substances present are trimethyleneglycol, glycerol, and water. Thus, for example, suppose x is the true glycerol content and y the amount of trimethyleneglycol, then:—

$$\text{Sp. gr. of mixture} = 1 + 0.00263x + 0.00053y$$

$$\text{App. glycerol content} = x + 0.81y.$$

From these two equations the unknown factors, x and y , can be calculated. This indirect method of analysis fails when less than 1% of trimethyleneglycol is present. In this case, it is necessary to fractionate the glycerin and submit the fraction boiling at 110°–280° C. to analysis as described above. As an illustration of the method the following example is given: A known amount (2500 grms.) of crude glycerin from a No. 2 whale oil was fractionally distilled at 80 mm. pressure, the distillation being continued until the temperature had reached and been maintained for some time at the boiling point of glycerol. The distillate (250 grms.) presumably contained all the trimethyleneglycol which was originally present in the crude glycerin; it was again fractionated under diminished pressure and the following fractions collected:—

a. Distilling up to 80° C. at 85 mm.	75 grms.
b. " from 80° to 215° C. at 85 mm.	12 "
c. " from 215° to 220° C. at 85 mm.	50 "

The trimethyleneglycol, if present, would be contained in the fractions a and b ; these were therefore distilled at the ordinary pressure, using a small fractionating column. The fraction 110°–280° C., amounting to 8 grms., was analysed, with the following result: Sp. gr. 1.0324; apparent glycerol 15.6%. Using the figures in the equations quoted above, it is found that the 110°–280°

fraction contains trimethyleneglycol 5.9%, glycerol 10.8%, water 83.3%. This amount of trimethyleneglycol corresponds with 0.02% on the original crude glycerin.

This method of examination was applied to a number of crude glycerins from whale oils of different quality, the results obtained being as follows:—

Whale oil.	Source of the glycerin.	Glycerol content.	Trimethyl- eneglycol.
No. 0	Saponification process	85.0	Nil
0	Autoclave	78.0	
*2	Twitchell	93.3	0.02
*2	Autoclave	80.0	0.05
3	Saponification	77.5	0.07

* These were different specimens of No. 2 whale oil.

It is evident from these figures that the crude glycerins contain only a very small proportion of trimethyleneglycol, and as this amount would be still further reduced by distillation, it may be concluded that the effect of trimethyleneglycol as an impurity in dynamite glycerin from whale oil of quality No. 0 to quality No. 3 is negligible.

It yet remained to ascertain what amount of trimethyleneglycol is contained in glycerin from the worst quality whale oil. For this purpose, several No. 4 whale oils were obtained and the worst of them selected for examination. This particular whale oil contained 56% of free fatty acid as well as an excessive nitrogen content, and evidently fermentative changes had taken place, which should be favourable to the production of trimethyleneglycol. A quantity of this oil was therefore hydrolysed by the autoclave process and the glycerin water evaporated to a syrup. For the distillation 1500 grms. was taken, distillation in this case being effected by means of superheated steam under diminished pressure and the vapours condensed in a series of air condensers as in large-scale practice. After about 30% of the mixture had distilled, the distillates in the various receivers were analysed with the following results:—

	Amount.	Sp. gr.	App. glycerol.	Trimethyl- eneglycol (calculated).
1st Receiver	grms. 160	1.1913	81.0	14
2nd "	60	1.0462	24.4	11.0
3rd "	80	1.0011	—	—

From these figures it is evident that fractions Nos. 1 and 2 contain an amount of trimethyleneglycol corresponding to 1.9% of the original crude glycerin.

It may be concluded from these results that crude glycerin from whale oil of very poor quality contains comparatively large proportions of trimethyleneglycol, and is not suitable for the production of dynamite glycerin.

2. Examination of whale oil glycerin for nitrogenous substances.

Whale oil of poor quality frequently contains a considerable proportion of nitrogenous matter, and it is therefore to be expected that crude glycerin from such oils would also be contaminated with nitrogen compounds. Since the presence of these impurities might conceivably lead to complications during the manufacture of dynamite, it was desirable that the matter should be further investigated. Accordingly a number of crude glycerins were prepared from whale oils of varied quality and the nitrogen content of each determined. The nitrogen determination was effected by heating 1–2 grms. of the material with sul-

phuric acid (Kjeldahl), then distilling with alkali and estimating the ammonia in the distillate by means of Nessler's reagent. In the cases where considerable ammonia was present, the ammonia was absorbed in *N*/10 sulphuric acid and the excess acid titrated. Blank experiments were also carried out to correct the results for traces of nitrogen in the reagents. The results of these experiments are given in the following table:—

Source of glycerin.	Total nitrogen.	Glycerol.
	%	%
From No. 0 whale oil—		
By the autoclave process	0.025	85.0
" saponille "	0.032	70.0
" Twitchell "	0.076	88.0
From No. 2 whale oil—		
By the autoclave process	0.035	80.0
" saponille "	0.012	80.0
" Twitchell "	0.092	88.0
From No. 3 whale oil—		
By the autoclave process	0.026	87.0
" saponille "	0.032	77.5
" Twitchell "	0.021	84.0
From No. 4 whale oil—		
By the autoclave process	1.10	74.0
" Twitchell "	2.03	82.0

The crude glycerins examined in the above manner were all prepared on a fairly large scale (100 lb.). For the purpose of comparison another series of crude glycerins were prepared on the laboratory scale under carefully controlled conditions. In this case the nitrogen content of both the original oils and the crude glycerins was determined with the following results:—

Source of glycerin.	Nitrogen in the original oil.	Nitrogen in the crude glycerin.
	%	%
No. 0 whale oil, Twitchell process	0.0014	0.007
No. 3 " " "	0.0042	0.010
No. 4 " " "	0.35	1.35
Cotton seed oil, " "	—	0.001
Palm kernel oil, " "	0	0

It may be concluded from these results that the percentage of nitrogen in the crude glycerin from the best quality whale oil is about the same as that in glycerin from good vegetable oils. It is only when the whale oil is of very poor quality that the amount of nitrogenous impurity in the crude glycerin is at all considerable. It is also evident that a considerable proportion of the nitrogen originally in the whale oil is ultimately found in the crude glycerin. If all the nitrogen of the oil passes into the crude glycerin the percentage of nitrogen in the latter will be approximately ten times that of the former.

3. The fate of the nitrogenous matter in impure glycerin during distillation.

As already shown, crude glycerin from poor quality whale oil contains an excessive proportion of nitrogenous impurities. It was, therefore, important to ascertain the effect of distillation on the nitrogenous matter and whether any appreciable quantity of nitrogen passes into the distillate. For this purpose two crude glycerins were examined, viz., a crude glycerin containing a comparatively large proportion (1.1%) of nitrogen, derived from No. 4 whale oil, and a crude glycerin containing 0.032% N. obtained from a No. 3 whale oil. The distillations were effected in a current of superheated steam (300° C.) and at a pressure of 85 mm., the crude glycerin being heated throughout in an oil bath at 230°–210° C. The condensers consisted of three air-cooled vessels in series, followed by a final water-cooled con-

denser; this system of distillation being a close imitation of large-scale practice. The results obtained were as follows:—

	Amount.	Nitrogen content.	Glycerol content.
	grms.	%	%
Crude glycerin from No. 3 whale oil	475	0.032	77.5
Distillate in 1st receiver	180	0.015	95.9
Distillate in 2nd receiver	65	0.07	29.0
Residue undistilled	200	—	—

The distillate in the first receiver gave a slight opalescence with phosphotungstic acid in the presence of sulphuric acid, whilst that in the second receiver gave a slight precipitate with this reagent.

	Amount.	Nitrogen content.	Glycerol content.
	grms.	%	%
Crude glycerin from No. 4 whale oil	1500	1.1	74.0
Distillate in 1st receiver	160	0.53	81.0
Distillate in 2nd receiver	60	0.95	24.1
Residue undistilled	920	—	—

Each of the distillates gave a strong precipitate with phosphotungstic acid in the presence of 5% sulphuric acid.

From these results it is clear that some of the nitrogenous matter of crude whale oil glycerins is volatile and that a considerable proportion of it collects in the first receiver containing the best distillate. Thus in the case of glycerin from No. 4 whale oil, the first portions of the distilled glycerin (dynamite glycerin) contained as much as 0.5% of nitrogen in the form of an organic base. It can be concluded, therefore, that crude glycerin containing an excessive proportion of nitrogen (above 0.1%) is unsuitable for the manufacture of dynamite glycerin unless further purification is undertaken.

The chemical nature of the nitrogenous substances in whale oil glycerins.

Having ascertained that whale oil glycerin contains, under certain circumstances, nitrogenous bases, it became a matter of some interest to consider whether any light could be thrown on the chemical character of these substances. There is no doubt, in the first place, that the basic substances in crude glycerin are derived from the proteins originally present in the oil. During the hydrolysis of the oil, this protein would be converted into amino-acids, the greater portion of which would pass into the crude glycerin. On distilling the glycerin the amino-acids, although not directly volatile, would yield by decomposition volatile bases. We should, therefore, expect to find, in the distillates from such glycerins, the decomposition products of amino-acids. In the case of vegetable oils the amount of protein or albuminous matter is usually very small and the crude glycerin from the oils is practically free from nitrogen. On the other hand, in the case of fish oils, the proteins are usually present in much greater amount, and are partly converted during hydrolysis and distillation into aromatic bases, which have about the same degree of volatility as glycerin and are, therefore, not easily separated from the latter by distillation. Moreover, Gautier and Etard* have isolated from putrid mackerel a base boiling at 210° C., which they considered to be identical with dihydrocollidine, whilst Conine†

*Comptes rend., 1883, 97, 263.

†Comptes rend., 1888, 108, 1601.

obtained from cuttle fish a similar pyridine base, and it is therefore probable that poor quality whale oil—and glycerin from the same—would contain pyridine bases.

Attempts were made to obtain some experimental support for the above suggestion that the bases present in distilled glycerin from whale oil of poor quality consist of pyridine derivatives. Two methods of isolation were investigated, viz., direct extraction from the glycerin by means of ether, and secondly precipitation of the base in the form of its phosphotungstate and the regeneration of the base from the precipitate (Barger, "Simpler Natural Bases," p. 118). By both methods of extraction the base was obtained as a dark brown oily substance possessing an odour suggestive of stale tobacco. Efforts were made to isolate from it definite crystalline derivatives with gold chloride and platinic chloride, but the aurochlorides and the platinochlorides produced were indefinite and amorphous. The odour of these bases certainly suggests that they contain pyridine derivatives, but the amount of substance available for investigation was too small to admit of definite identification of these substances.

In addition to the presence of pyridine bases in glycerin from whale oil of poor quality, it is also quite possible that acid amides may be present. Thus the fermentative changes occurring in whale oil would produce, amongst other substances, ammonia and volatile fatty acids (acetic acid, etc.), and these would appear in the crude glycerin as ammonium salts. In the subsequent distillation the ammonium salts would be converted into amides (acetamide, b.pt. 220° C.), which are volatile and would contaminate the distillate.

To test the correctness of this suggestion, a distillation experiment was carried out with glycerin mixture known to contain ammonium acetate. The crude glycerin mixture was made up as follows:—82% double distilled glycerin (free from nitrogen), 8% water, 2½% sodium chloride, 2½% ammonium acetate, and 5% sodium acetate. The resulting distillate (92% glycerin) contained no free ammonia, but when heated with alkalis gave a decided ammoniacal odour. It seems, therefore, safe to conclude from this experiment that part of the nitrogen in distilled glycerin from whale oils of poor quality is in the form of an amide.

4. The possible effect of trimethyleneglycol and nitrogenous substances on the nitration of glycerin.

It has been shown in the previous part of the investigation that distilled glycerin from whale oils is liable to contain as impurities trimethyleneglycol and nitrogenous bases. The question now arises whether these substances would have any effect on the course of the nitration when using such glycerin for the manufacture of nitroglycerin. Considering the matter theoretically, it is very doubtful whether small quantities of trimethyleneglycol would have any deleterious influence on the nitration process. On the other hand, small quantities of nitrogenous bases and amides would possibly induce decomposition of the nitrated mixture with dangerous results, especially as it is known that acid amides are decomposed by cold nitric acid, with liberation of nitrous oxide. Obviously the best method of ascertaining the effect of impurities in the course of nitration would be to carry out actual nitration experiments. Such experiments, however, we have not undertaken, but we have been able to show that, when the nitrogenous bases are isolated from impure whale oil glycerin and then treated with a cold nitrating mixture of sulphuric acid and nitric acid, decomposition with gradual evolution of gaseous matter takes place. It may, therefore, be reasonably concluded that it would be dangerous to nitrate

glycerin containing a moderate amount of such impurities.

Conclusions.

1. The best varieties of whale oil (No. 0) yield glycerin equal in quality to that from vegetable oils and may therefore be safely used for the manufacture of dynamite glycerin.

2. Medium quality whale oils (Nos. 1—3) yield distilled glycerin containing minute quantities of trimethyleneglycol and nitrogenous matter. The amount of impurity is, however, too small to affect the glycerin deleteriously.

3. Very inferior whale oils (No. 4 quality) are unsuitable for the production of dynamite glycerin, and should be rejected. Such oils may be recognised by their high nitrogen content and high percentage of free fatty acid and by the fact that distilled glycerin prepared from them gives a precipitate with phosphotungstic acid in the presence of 5% sulphuric acid. In general, if a sample of glycerin responds to the latter test, it should be rejected.

ON THE QUALITY OF GLYCERIN FROM WHALE OIL.

PART II.—AN INVESTIGATION OF THE FACTORS INFLUENCING THE QUALITY OF CRUDE GLYCERIN WHEN MANUFACTURED BY THE TWITCHELL PROCESS.

BY L. V. COCKS AND A. H. SALWAY.

In the first part of this investigation the quality of crude glycerin from whale oil was estimated by the proportion of trimethyleneglycol and nitrogenous substances found in the material. In practice, however, the percentage of ash and organic residue is usually taken as a measure of the quality of the glycerin. This method of analysis was applied to the crude glycerins described in the foregoing paper, but it was soon found that, although the organic residue is influenced to some extent by the quality of the whale oil, other factors depending on the process of hydrolysis tend to obscure the results and prevent definite conclusions being drawn. It was therefore desirable that an investigation of the factors influencing organic residue in glycerin obtained by various methods of hydrolysis should be undertaken, and to this end a commencement has been made with the Twitchell process as described in the present paper.

The quality of crude glycerin obtained by the Twitchell process may be influenced by the quality of the Twitchell reagent and also by the quality of the oil employed. The influence of each of these factors on the quality of the glycerin was investigated separately. In all cases, unless otherwise specified, the glycerin was prepared by hydrolysing the oil with 1% of Twitchell reagent in the presence of 2% of sulphuric acid, the mixture being steamed for 8 hours, which usually caused about 70% hydrolysis. To prevent excessive condensation of steam during hydrolysis, the mixture was gently heated from without. The glycerin waters separating at the conclusion of the operation were carefully neutralised with milk of lime, then filtered and concentrated under diminished pressure until the glycerin was about 50% strength. At this stage the liquor was again filtered to remove calcium sulphate and finally further concentrated to 88% glycerin.

1. The influence of the Twitchell reagent.

Some of the organic residue in crude glycerin obtained by the Twitchell process is undoubtedly derived from the Twitchell reagent, and it was therefore of importance to determine what contribution the latter makes to the total organic residue. In most of the experiments recorded

in this investigation the reagent employed was a so-called double saponifier of commercial origin, but in a few experiments another type of saponifier, acid in character and almost entirely soluble in water, was employed. The effect of each of these saponifiers on the organic residue was determined by the following method: A known weight of the Twitchell reagent was mixed with dilute sulphuric acid and the mixture heated with open steam for 8 hours. The liquid was then neutralised with lime, filtered, and the organic residue in the filtrate determined in the same way as in glycerin analysis. The results were as follows:—

Materials used.	Organic residue calc. on original saponifier.
	%
Double saponifier—	
1 pt. saponifier	5.2
1 pt. sulphuric acid	
20 pts. water	
Soluble saponifier—	
1 pt. saponifier	12.5
0.1 pt. sulphuric acid	
20 pts. water	

From these results a simple calculation will show how much organic matter the Twitchell reagent will introduce into the crude glycerin during hydrolysis. Suppose 1% of reagent is employed and the hydrolysis is carried to 70% free fatty acid, as in the majority of the experiments herein recorded, then the amount of reagent per 100 parts of crude glycerin (88%) is 12.7 parts, of which 5.2% in the one case and 12.5% in the other case passes into the glycerin as organic residue. Hence the amount of organic residue in crude glycerin due to the double saponifier is

might be expected to be inferior to the glycerin from vegetable oils. In order to ascertain the difference between glycerins from a vegetable oil and from whale oil of poor quality, the following experiment was undertaken. Whale oil of No. 3 quality, containing 13.8% of free fatty acid and 0.021% of nitrogen, was hydrolysed with Twitchell reagent in the manner described in the introduction to this paper. The glycerin obtained (88% strength) was compared with the glycerin prepared in a similar manner from refined palm kernel oil, when results were obtained as follows:—

	Extent of hydrolysis.	Organic residue.	Calc. organic residue due to Twitchell reagent.	Difference.
		%	%	%
No. 3 whale oil	78% in 8 hrs.	1.23	0.73	0.50
Palm kernel oil	74% in 8 hrs.	0.70	0.62	0.08

It is thus evident that there is more organic residue in the crude glycerin from No. 3 whale oil than in the glycerin from palm kernel oil. Presumably the difference is due to the nitrogenous matter in the whale oil. To get a clearer idea of the effect of nitrogenous substances it would be of interest to examine a series of oils of varying nitrogen content, but as most whale oils contain only a comparatively small amount of nitrogen it was decided to test the effect of adding nitrogenous matter to palm kernel oil and then preparing and examining the glycerin from the impure oil. This was done with the following results:—

	Extent of hydrolysis.	Glycerol.	Organic residue.	Calc. organic residue due to Twitchell reagent.	Difference.
		%	%	%	%
Pure palm kernel oil	72% in 6½ hrs.	88	0.45	0.61	—
Do. with 0.1% casein (N=0.016%)	68% in 6 hrs.	88	0.97	0.68	0.29
Do. with 0.5% casein (N=0.083%)	66% in 6 hrs.	88	3.70	0.70	3.00
Do. with 1.0% casein (N=0.166%)	51.5% in 7 hrs.	88	9.26	0.90	8.36

0.66% and that due to the soluble acid saponifier is 1.59%.

In order to see whether these figures would be corroborated in practice, several oils were hydrolysed with the two Twitchell reagents, and the crude glycerins (88%) analysed with the following results:—

	Extent of hydrolysis.	Organic residue found.	Organic residue due to Twitchell reagent.
		%	%
1% Double saponifier. {Palm kernel oil	74% in 8 hrs.	0.70	0.62
1% Double saponifier. {Refined whale oil	78.2% in 8 hrs.	0.59	0.58
1% Soluble acid sapon. {Palm kernel oil	63% in 11 hrs.	1.90	1.77
1% Soluble acid sapon. {Refined whale oil	68.7% in 8 hrs.	2.40	1.62

It is clear from these figures that good agreement results, except in the last case, and it may be concluded that when hydrolysing a good oil, as for example palm kernel oil, under the aforementioned conditions, practically all the organic residue in the crude glycerin comes from the Twitchell reagent.

2. Influence of the quality of the oil.

Effect of nitrogenous matter.—It is generally considered that the presence of nitrogenous substances in an oil will seriously affect the quality of the crude glycerin, and, as whale oil is particularly liable to be contaminated with such impurities, the crude glycerin from the latter

method prescribed above, then the following generalisation may be made:—

0.02% N in an oil gives 0.5% organic residue to the crude glycerin.
0.035% N " " " 1.0% " " " "
0.06% N " " " 2.0% " " " "
0.085% N " " " 3.0% " " " "
0.10% N " " " 4.0% " " " "

It was next of interest to see how far these figures agree with the experimental results obtained when hydrolysing whale oil of known nitrogen content. For this purpose, whale oils of No. 1 and No. 3 quality were hydrolysed under the specified conditions with the following results:—

	Free fatty acid.	Nitrogen.	Extent of hydrolysis.	Organic residue.		Found.
				Due to Twitchell reagent.	Due to nitrogen.	
No. 1 whale oil	7.4	0.002	78.2% in 8 hrs.	0.62	0.65	0.59
Unrefined No. 3 whale oil	13.8	0.021	78% in 8 hrs.	0.73	0.50	1.23
Refined No. 3 whale oil	14.0	0.001	—	0.72	0.02	0.68

It is thus clear that the organic residue determined experimentally in the above crude glycerins is approximately the sum of the organic residue contributed by the Twitchell reagent, and the organic residue calculated from the nitrogen content of the oil on the basis of the figures already quoted.

Incidentally the figures show also that the crude glycerin from properly refined whale oil is equal in quality to the glycerin from vegetable oils.

Effect of oxidation.—In connection with these experiments it seemed desirable to ascertain whether an oxidised oil would yield a glycerin with higher organic residue than glycerin from an unoxidised oil. For this purpose a No. 3 whale oil (free fatty acid 15.1%) was divided into two portions. One portion was heated to 100° C. and a current of air passed through it at this temperature for 6½ hours, after which it was hydrolysed in the usual way. The unoxidised portion was hydrotysed in the same way for comparison. In the first case the organic residue of the crude glycerin (88%) was 1.09%, whilst the unoxidised oil gave a glycerin with 1.03% of organic residue. The treatment with air, therefore, had no appreciable effect on the glycerin quality, and it may therefore be concluded that whale oil may be exposed to atmospheric oxidation without influencing the quality of the glycerin.

Summary and conclusions.

The various factors influencing organic residue in crude glycerin obtained by the Twitchell process have been investigated. It has been shown that the chief factors are:—

1. The quality of the Twitchell reagent.
2. The nitrogenous matter in the oil.

A method is described for determining the proportion of organic residue due to the Twitchell reagent, and figures are given enabling the organic residue due to nitrogenous matter to be calculated from the nitrogen content of the oil. Under good conditions of working the organic residue should be the sum of these two figures.

The authors, in conclusion, desire to acknowledge their indebtedness to Messrs. Lever Bros., in whose research laboratories the investigation was undertaken, and to the Ministry of Munitions, for permission to publish those parts of the research which are of general interest.

Discussions on Papers.

UTILISATION OF NITRE CAKE.

Mr. J. N. STEPHENSON, of Montreal, writes as follows:—

In the discussion on nitre cake in the December 15th (1917) issue of the Journal (pp. 1216 A—B), no mention was made of its use in the pulp and paper industry. For some time experiments have been made and some application has resulted in connection with the use of nitre cake to replace part of the alum used in the engine sizing of paper. Substitution to the extent of some 35% of the alum previously used has been claimed to have been effected. Another use would apply to the manufacture of sulphate or "kraft" pulp. In this

process sodium sulphate or salt cake is the material generally employed and during the incineration of the evaporated waste liquors this is reduced to sodium sulphide, other sodium salts being converted to sodium carbonate which is later causticised with lime. The use of nitre cake entails some difficulties which have been satisfactorily overcome by some pulp mills. It will be seen that acid sodium sulphate will furnish only half the sodium sulphide which can be derived from salt cake. It will be further observed that the action of acid sulphate will convert sodium carbonate to sodium sulphate with the liberation of carbon dioxide, which it is not desirable to have in the furnace. The acid will also convert the sodium sulphide into hydrogen sulphide. This action has the further disadvantage of destroying the sodium sulphide, the presence of which is desired in the process. If the action of the nitre cake is allowed to proceed where the gaseous products may freely enter a room in which workmen are employed there is danger of suffocation by the carbon dioxide and of poisoning by the hydrogen sulphide unless the acid character of the nitre cake is first neutralised. Of the two dangers, that from the hydrogen sulphide is undoubtedly the more serious. In fact, several deaths have resulted from improper use of this material. With proper handling, however, nitre cake is entirely satisfactory in the pulp mill.

RECOVERY OF POTASH FROM BLAST FURNACE GASES.

Mr. E. H. LEWIS, of the Glasgow Iron and Steel Co., sends the following particulars of the amount of potash charged into their blast furnace during the month of October, 1917, for comparison with the figures given by Professor Berry (this J., 1918, 23 T):—

Charged into furnaces.	% K ₂ O.	Lb. of K ₂ O per ton of pig iron produced.
Iron ores	0.13	5.16
Coal and coke	0.05	2.15
Limestone	0.101	0.81
		8.12
Recovered.		
Slag	0.146	1.63
Pitch	1.20	2.67
Tube cleanings	2.23	0.07
Dirt from washers	1.20	0.07
Heavy dust from tubes	0.20	
Waste liquor.....	2.49	1.58
	grains per gall.	
Less in running off slag and unaccounted for		6.02
		2.10
		8.12

Meeting held at Montreal on Friday, January 25th, 1918.

MR. T. H. WARDLEWORTH IN THE CHAIR.

THE WASTE SULPHITE LIQUOR PROBLEM.

BY BJARNE JOHNSEN.

The pulp obtained by heating wood at high temperature and pressure with a solution of calcium and magnesium bisulphites represents only about 50% of the dry weight of the wood, while the other 50% of the wood substance is contained in the waste liquor, which is not at present utilised in Canada. The utilisation of this waste has always been one of the great problems of the sulphite pulp industry, especially in countries which do not possess large forests, as well as in countries where legislation has prohibited the discharge of waste sulphite liquor into rivers which are too small to afford the dilution of the liquor, which is considered necessary to prevent injury to fish life.

It is not necessary to mention all the processes which have been proposed for the utilisation of waste sulphite liquor during the last 40 or 50 years: it will suffice to say that they involve uses of a most varied nature, such as the manufacture of tanning materials, cattle food, dyestuffs, preservative for eggs, ethyl alcohol, etc. The object of this paper is to report on certain modern processes, which in some places have gained industrial importance and which might be introduced with advantage into Canada.

According to Klason the chief constituents of European spruce wood average as follows:—Cellulose 50%, lignin 30%, carbohydrates 16%, protein 0.7%, resins and fats 3.3%. As most of the analytical work on waste sulphite liquor has been carried out in Europe the figures given below are based upon the composition of the liquor obtained from the cooking of this material. In Canada various species of spruce, fir, and hemlock are used in the manufacture of sulphite pulp. These woods vary considerably in their chemical composition, the cellulose content of white spruce, for example, being about 4 or 5% higher than that of balsam fir or hemlock and the lignin content also varying within 4 or 5% in the different species. The same is true of the carbohydrates and of tannin, the amount of the latter being very low in the spruces and in balsam fir. The composition of the wood also varies in the same tree with the dimensions and the conditions of growth. As to the nature of the substances mentioned above our knowledge is still very limited. Klason considers the lignins to consist of condensation products of coniferyl alcohols and therefore to contain an aromatic nucleus. He also assumes the presence of three ethylene groups and an active carbonyl group which are able to combine with the sulphurous acid of the cooking liquor. On the basis of these assumptions we may consider the main reaction between the lignin complex and the cooking liquor as consisting of an addition of SO_2 to the lignin complex forming sulphonie acids, the barium salt of which has been isolated from the waste liquor by Klason, who established for this compound the empirical formula $\text{C}_{10}\text{H}_{14}\text{O}_{17}\text{S}_2\text{Ba}$, with a molecular weight of at least 6000, which indicates the formula for lignin to be $(\text{C}_{10}\text{H}_{12}\text{O}_{11})_n$. The lignin compound is further characterised by a number of reactions showing for instance the presence of methoxyl and acetyl groups. A further action of the liquor in the cooking process

is the hydrolysis of the polysaccharides of pentoses and hexoses which are thereby converted into soluble sugars. The cooking process must be regarded as consisting of a great number of both complicated and simple reactions, which with our present limited knowledge of the constitution of wood we are unable to follow in detail. This fact, as well as the variation in the wood and in the method of cooking, makes it impossible to form any definite opinion with regard to the quantitative composition of the waste liquor, but the composition of the wood substance on the one hand and the purity of the wood pulp obtained on the other hand, as far as we possess methods for determining these factors, give us an idea of the substances which may be expected in the waste liquor.

Waste sulphite liquor has a specific gravity of about 1.05, gives an acid reaction, has a strong reducing power, and contains about 12% of organic and 1 to 1.5% of inorganic substances. The latter originate mainly from the cooking acid but partly from the inorganic substances of the wood, which represent about 0.25 to 0.5% of the dry weight of the wood. Sulphurous acid is present to some extent in the free state and partly so loosely combined with organic substances that it may be removed by heating. Most of the sulphurous acid is, however, present in the form of sulphonie acids. The liquor also contains small quantities of sulphuric, acetic, formic, and oxalic acids as well as traces of citric acid, small quantities of vanillin, furfural, and succinic and protocatechuic acids. A precipitate obtained by addition of animal glue has been used as a reaction for tannin compounds, but the presence of such compounds, at least in any appreciable quantity, is questioned by the tanning industry.

The following summary of the constituents of the waste liquor has been calculated by Klason on the basis of a short ton of pulp:—

	Liquor I.	Liquor II.
	lb.	lb.
Lignin	1287	1290
Carbohydrates	622	650
Proteins	31	30
Resins and fats	146	60
Sulphurous acid combined with lignin	470	400
Lime	204	180
	2700	2520

The theoretical yield of by-products is often calculated upon a recovery of up to 1800 gallons of liquor per ton of pulp, which represents very nearly the total liquor in the digester. As a matter of fact, only about 710 gallons will drain off from the blow pits per ton of pulp, while probably a maximum of 800 gallons could be obtained if the draining were continued for a longer period without the use of any special equipment.

The liquor might now be utilised in one of different ways, either by recovering the total solids as a whole or by isolating one or more of the most valuable constituents. The former method, involving more or less complete evaporation, has been employed at places where a discharge of the waste liquor into the rivers is prohibited. The concentrated liquor is a tar-like product with binding properties, and has therefore been proposed as a binder for powdered materials and for roads. As a result of extensive experiments the U.S. Department of Agriculture classifies concentrated sulphite liquor of specific gravity 1.13 as a temporary or semi-permanent road binder and dust preventive. One half gallon per square yard was found to be effective for a period of six weeks. The cost,

including labour and material, was estimated at \$0.0355 per square yard. Favourable results have also been secured at Queen's University using concentrated liquor as a road-binder. The binding and water-resisting qualities may be improved by emulsifying the liquor with a mineral oil.

It is often desired to remove the lime from the liquor, and this can be effected by the addition of sulphuric acid or a soluble sulphate with subsequent filtration. This is no doubt especially desirable when the concentrated liquor is to be used as a binder for powdered fuel, blast furnace dust, fine pyrites, or foundry core sand. In all these ways the waste sulphite liquor has been used successfully. The hygroscopicity and solubility in water of the binder from waste liquor have been pointed out as drawbacks in its use as a binder for fuel. Several methods have been proposed for the elimination of this disadvantage, such as carbonisation of the binding material at a high temperature or the addition of chromium salts and finally aluminium sulphate. The briquettes may also be immersed in a mixture obtained by heating crude petroleum oil with bitumen or phenols to the boiling point, with strong aeration, until a mixture is obtained which solidifies on cooling.

The product known as "Zellpech" or "Cell pitch" is waste liquor neutralised and filtered through coke and afterwards concentrated to 35° B. or to a solid substance of 10% moisture content. One ton of coal is required to produce a ton of "Cell pitch," the heat value of which is 5700 B.Th.U.

An adhesive can also be obtained if the waste liquor is concentrated after the addition of zinc carbonate or oxide, or if the liquor is concentrated *in vacuo* with an excess of magnesium oxide with magnesium chloride added in a proportion equivalent to the excess of magnesium oxide, in order to form the oxychloride. Usually, however, the adhesives are obtained by precipitation with glue or albuminous substances.

A tanning material can be obtained by concentrating the liquor to about 30° B., but it is necessary to remove certain impurities which are detrimental to leather, such as lime, iron, and the free and loosely combined sulphurous acid. The sulphurous acid can be removed by evaporation, with or without the addition of sulphuric acid, or may be precipitated as calcium sulphite by the addition of the required quantity of lime. The organically combined lime is usually removed by precipitation with sulphuric acid or a soluble sulphate. Oxalic acid is often recommended for the removal of the last trace of lime, or lactic acid is used since the resulting calcium lactate has no injurious effect upon the leather. There are a great number of more complicated methods for obtaining a tanning material from waste sulphite liquor, such as the addition of the sesquioxide of aluminium or chromium, the precipitation of an organic cyanogen compound from the liquor after a previous heating with potassium or sodium cyanide, etc.

The tanning value of these extracts, known on the market as "sulphite extract," "spruce extract," "Norego," etc., has been the subject of lively discussion. It has been claimed by tanners that these extracts have no tanning value because they do not contain tannin, or at least only very small quantities. This is true, and the reactions obtained from sulphite liquor with glue and with iron solutions, which have been assumed to be reactions of tannin, must be due to the sulphonic acids of the lignin. However, experiments have shown that hide absorbs as much as 23—25% of substances from a "sulphite extract," being transformed into leather which has in some cases surpassed both hemlock and oak leathers in quality. It is not recommended to use these "sulphite

extracts" alone, as the best results are obtained in admixture with other extracts, for example quebracho extract, since the "sulphite extract" is a good solvent for the difficultly soluble portions of the quebracho extract, namely, the phlobaphenes. It is also possible by employing "sulphite extract" in mixture with other extracts to obtain a proper proportion between the tannin and non-tannin substances, and to accelerate the tanning process. The low cost of "sulphite extract" ($\frac{3}{4}$ —1 cent per pound) results in a considerable saving. The opposition of the tanning industry to this extract may be due to the poor quality of the first products put on the market, but it is generally admitted by the tanners that for certain leathers "sulphite extract" may be used with great advantage and, as a matter of fact, tanning extracts from waste liquor are at the present time imported to Canada and used quite extensively in Canadian tanneries.

It was mentioned above that the "cell pitch" obtained by evaporation of the waste liquor had a heat value of 5700 B.Th.U. but even with modern evaporators a recovery of this product for use as a fuel would hardly be economical. Strehlenert's process for manufacturing fuel from waste liquor is based upon the precipitation of the lignin compounds at high temperature and pressure. The decomposition is effected by the sulphuric acid which is formed from the sulphurous acid present in the liquor. According to the first patents the formation of sulphuric acid is effected by oxidation at a comparatively low temperature by the introduction of air or oxygen into the autoclave. The reaction $4\text{CaSO}_3 = 3\text{CaSO}_4 + \text{CaS}$ takes place subsequently. As copper autoclaves are used copper oxide and finally copper sulphate are formed and the following reactions take place:

The copper therefore causes the direct formation of fresh quantities of sulphur dioxide. It is found, however, that the presence of even small quantities of iron, zinc, manganese, or other hydrogen-forming metals decreases the yield of precipitate considerably. By introducing the air at a higher temperature the oxidation and decomposition take place simultaneously and so rapidly that the action of the metal is eliminated. The formation of SO_3 at lower temperatures is avoided by introduction of SO_2 from the sulphite digesters. When the sulphuric acid is formed at high temperatures the reaction may be expressed by the equation: $3\text{SO}_2 = 2\text{SO}_3 + \text{S}$, and theoretically no air is required. But the presence of air is of advantage, as it causes the organic compound to be precipitated in a coarser form. The new autoclaves are lined with lead to prevent the reaction between the SO_3 and the autoclave material. The reactions may then be expressed as follows:—

In this process only 75% of the total solids is precipitated, and Strehlenert concludes that this portion consists of compounds of sulphinic acids, the remaining 25% consisting of sulphonic acid compounds. In his calculations Strehlenert assumes a liquor recovery per ton of pulp of 1200 gallons, or 1800 gallons when diffusers are used. He also assumes the most favourable conditions with regard to yield and to the concentration of the liquor (namely, 17% solids). The operating cost per short ton of fuel in a Scandinavian plant is \$2.88, according to Strehlenert's calculations, including depreciation, labour, and repairs, assuming a recovery of 1200 gallons of waste liquor per ton of pulp in a plant having a capacity of about 20,000 tons of pulp per year. But this fuel is of an inferior quality, containing about 18%

ash and about 50% of water. Considering these two points the cost would be equivalent to \$1.75 per short ton of good coal of 11,100 B.Th.U.

Assuming the concentration of the waste liquor to be 11%, however, and considering the higher cost of labour, etc., in North America, the manufacturing cost of recovered fuel will be equivalent to \$6.80 per ton of good coal of 11,100 B.Th.U. on the basis of a 33,000-ton pulp mill and a recovery of 800 gallons of liquor (328 lb. of fuel) per ton of pulp. On the basis of 1200 gallons of liquor (492 lb. of fuel) per ton of pulp, the manufacturing cost of recovered fuel would be equivalent to \$6.35 per short ton of coal of 11,100 B.Th.U.

This cost could probably be somewhat reduced by the recovery of by-products such as acetone, acetic acid, formic acid, and methyl alcohol, but in the present form this process would hardly be of practical interest to the Canadian industry. Under the conditions, however, which at present prevail in Scandinavia the process is of considerable value. At least one plant is in operation in Norway, and orders have been placed for several plants of the same type in Sweden, Finland, and Russia.

When certain by-products are recovered by destructive distillation the fuel process appears to better advantage. It has been found that distillation of the precipitate gives 56% of charcoal, 18.7% of crude acid, 2.1% of tar, and 23.2% of non-condensable gases and that there are present in the crude acid, on an ash- and water-free basis, 1.0—1.1% of methyl alcohol, 0.12% of acetone, 0.45% of acetic acid, and 0.014% of formic acid. The economy of destructive distillation of the residue has not yet been sufficiently investigated.

A process which has been more seriously considered in America is the manufacture of ethyl alcohol from waste sulphite liquor. The amount of fermentable sugars in the liquor varies considerably since their formation from the lower hexosans of the wood as well as their destruction in the cooking process depends largely upon the strength of the acid and the temperature during the last part of the process. Usually the liquor contains between 1.5 and 2% of fermentable sugars, but in some cases this value may be as high as 2.4%. Klason found a waste sulphite liquor to contain mannose 0.526%, galactose 0.274%, dextrose 1.65%. Of these sugars galactose ferments more slowly than the others, and the highest yields of alcohol obtained, namely, 1.4% by volume of the liquor, corresponds approximately to the mannose and dextrose content. On an average only 1% of alcohol is obtained on a commercial scale, although Landmark claims an average of 1.1% for his process, and the Marchand process is said to give 1.25% of alcohol.

The principle of the various processes of manufacturing alcohol from waste liquor is the same. The free sulphurous acid, which is strongly toxic to yeast, is partly removed by evaporation and partly by neutralisation to a point of acidity favourable for fermentation. The difference in the various processes lies mainly in the method of neutralisation. It is not advisable to neutralise with lime alone, as a large excess is required, causing the destruction of a large proportion of sugars and an undesirable turbidity of the liquor. In the Swedish plants which are operating under Ekström's and Wallin's patents, a smaller quantity of lime with the final addition of calcium carbonate effects the neutralisation. In Marchand's process barium carbonate is used, while in Landmark's only calcium carbonate is employed. The waste liquor does not contain nitrogen and phosphates in the quantity required for normal fermentation, and if yeast extracts which do not

contain the necessary amount of these substances are used they must be added to the liquor in a suitable form. In Ekström's process a "tempered yeast" is added which is prepared to meet the special condition of the sulphite liquor. This is not necessary in Landmark's process; in this case milk or whey is heated with acid, the precipitate of "lignocasein" (which can be used in paper sizing) is filtered off, and the filtrate added to the liquor, which can then be fermented directly with ordinary brewers' yeast. The cost of the milk is said to be covered by the value of the "lignocasein."

Haglund has calculated the cost of manufacturing 100% alcohol based upon a recovery of 800 gallons of liquor per ton of pulp. His calculations are based on 30,000, 20,000, and 10,000-ton mills in Scandinavia. However, if we assume for Canadian conditions that the costs of plant, labour, salaries, and repairs are 50% higher than in Scandinavia, and if we further allow 15% depreciation and interest, the total cost of one Imp. gallon of 100% alcohol will be \$0.220, \$0.251, and \$0.321 on the basis of a 30,000, 20,000, and 10,000-ton pulp mill respectively.

The manufacturing cost estimated by Landmark for his process is not directly comparable with the figures given above because he bases his calculations on a recovery of 1400 gallons of liquor per ton of pulp and upon a plant connected with a 15,000-ton mill. It is, however, possible to bring these calculations to a certain accordance with those used in the discussion of the previous process whereby the cost of production, including depreciation and interest and cost of handling, would be very close to \$0.19 per Imp. gallon of 100% alcohol, which is appreciably higher than the cost estimated by Landmark himself. With regard to the cost of production of alcohol, reference may be made to an article by Breckler (see J. Ind. Eng. Chem., 1917, 9, 612; this J., 1917, 902) giving the average cost of alcohol from grain for the past five years as high as 17.5 cents per proof U.S. gallon or about 24 cents per Imp. gallon, corresponding to \$0.48 per Imp. gallon of 100% alcohol, which is considerably higher than the cost of sulphite spirit. The crude sulphite spirit contains about 3% of methyl alcohol. The two alcohols can be separated, but this is not necessary as the spirit can be used in the crude form for industrial purposes, as motor fuel, for illumination and cooking, replacing gasoline and petroleum. In its eighth annual report, the Commission of Conservation points out the importance of establishing an alcohol industry as Canada is now dependent upon foreign sources for her supply of petroleum and petroleum products.

The production of sulphite spirit has already reached commercial importance in other countries. In Norway two plants are in operation, while four plants in Sweden are producing one million gallons per year and three more plants are being erected. In Germany 13 plants are being built or are probably now in operation and in the United States two, and in Switzerland one plant is operated. Considered from the standpoint of utilisation of waste liquor this process does not solve the problem completely, as the fermentable sugars represent only 15—20% of the total solids, but the remaining liquor may be used in one of the other processes, for instance, for the recovery of a binding material, or fuel, or for destructive distillation of the dry residue obtained by evaporation.

Waste sulphite liquor has also been suggested for use as a fertiliser, but in this case its value is only indirect as it contains the substances required for a good fertiliser in very small amounts. In mixture with other substances it may be of some value for poor soils because of its content of organic substances which form a good medium for the growth of nitrogen-forming bacteria.

As the amount of solid substance in the waste liquor is very low (only 11–12%), the economy of most of the processes suggested for its utilisation depends largely upon the cost of concentration. A much higher efficiency is claimed for a new type of evaporator which is now built in Sweden and by which the heat of the vapours from the liquor is utilised much better than in the usual multiple effect evaporators. Oman has recently announced a quite different method of concentration, namely, by freezing. The liquor can be concentrated to one-fourth of its original volume much cheaper than by evaporation. No details regarding this new process are yet available, and it would probably only be feasible in countries with cheap water power and high coal prices.

The Canadian sulphite pulp industry consumed in 1916 about 728,000 cords of wood. This means that approximately 1000 tons of wood substance was carried away daily as waste with the liquor, and it shows that it would mean a tremendous saving for Canada if existing processes could be adopted or new methods developed by which this waste could be eliminated or at least considerably reduced in an economical way.

In conclusion, I have to thank Mr. O. F. Bryant, of the Forest Products Laboratories, for the valuable assistance given me in the preparation of this paper.

THE DETERMINATION OF CELLULOSE IN WOOD.

BY DR. BJARNE JOHNSEN AND R. W. HOVEY, B.S.C.

The value of having a correct method for the estimation of cellulose in wood has been recognised for many years and has resulted in a large number of methods being proposed. It would be beyond the scope of this paper to review all these methods, but those who desire to make a detailed study of them are referred to the original works of Renker* and of König and Huhn† and to the references which will be found in the textbooks on cellulose published by Schwalbe‡ and by Cross and Bevan§. Generally it may be said of the methods of estimating cellulose that they, like the commercial processes for manufacture of wood pulp, are based upon the high resistance of the true cotton cellulose towards chemical reactions such as hydrolysis and oxidation and the comparatively low resistance of the non-cellulose substances. The disadvantage of these methods, however, is that they either do not effect a complete removal of the non-cellulose matters, or if they do, that the strong reagents employed also destroy part of the cellulose itself. Some of the methods which give a comparatively pure product are too complicated and require too much time.

There is, however, one method which has created more interest than the others, namely, Cross and Bevan's chlorination method. This method has been extensively used in scientific investigations and generally adopted by the industry. Its advantages are that the chief reaction, the chlorination of the lignin, has been comparatively well studied and is in itself a colour reaction which indicates when the purification is completed and finally that the method is carried out in a comparatively short time. The chlorination method has in recent years been considered to give the most satisfactory results, but the method has been carried out in so many different ways in the various investigations that the values obtained are hardly comparable. In an analytical study of the various Canadian wood species used in the paper industry

it was considered of significance to be able to determine the cellulose content with the greatest possible exactness. However, in adopting the chlorine method in this work it was intended by taking advantage of recent modifications and attempting further improvements to establish a standard method which could be recommended for future investigations.

The action of chlorine gas upon moistened vegetable fibres was originally studied by Cross and Bevan* in their investigation on jute fibre. They proved that with jute, which they consider as the typical form of "lignocellulose," the reaction with chlorine gas represents a chlorination of the lignin groups with the formation of a lignin chloride of the empirical formula $C_{19}H_{13}Cl_4O_9$, a yellow product which is soluble in absolute alcohol, in alkali, and in sodium sulphite. When sodium sulphite is added to the chlorinated product a red colour is at once produced, which can be considered as the most typical lignin reaction and therefore represents an excellent test for the degree of purification during the operation of the method, whereby unnecessary prolongation of the chlorination can easily be avoided. With jute the chlorination is apparently a simple replacement of hydrogen by chlorine without any secondary reactions, as it was stated by Cross and Bevan that hydrogen chloride was formed in the process to the same extent as chlorine was fixed to the lignin complex. With wood, considerably more chlorine is used for the formation of hydrogen chloride than is used in the formation of lignin chloride. This fact was observed by Cross and Bevan and it has been generally believed that this was caused by an oxidation of the cellulose. But Heuser and Siebert†, who studied this reaction with spruce wood more closely, and who confirmed Cross and Bevan's results, were able to prove that the lignin could be completely removed by the chlorination process without any oxidation of cellulose, and that therefore the large excess of hydrogen chloride must be due to reactions with chlorine, probably oxidation of non-cellulose substances. If, on the other hand, chlorine gas is allowed to act upon the cellulose residue for any length of time after the lignin has been removed, the cellulose is gradually transformed into oxycellulose, and this reaction is accompanied by a slight loss in weight of the substance when subsequently heated with sodium sulphite. Accordingly it is important to reduce the time of chlorination to a minimum. The chlorine gas reacts in the first place with the surface of the fibre, forming a layer of lignin chloride which very soon prevents the gas from acting on the interior of the fibre, and unless the lignin chloride is first dissolved a prolonged exposure to the gas has no favourable effect. The removal of the total lignin can accordingly only be effected by intermittent treatments with chlorine and sodium sulphite. This was shown distinctly by Siebert and Walter‡, who stated that the lignin could be totally removed from finely divided spruce wood in four chlorinations with a total time of exposure to the gas of one hour, if the periods of each chlorination were limited to 20, 15, 15, and 10 minutes, the chloride being dissolved in sodium sulphite after each period. This was found by the present authors to be true with all the Canadian species which have been analysed up to date. This is naturally only possible when the material used is a fine and uniform sawdust, which should be of such a fineness as to pass an 80-mesh sieve but not a 100-mesh sieve. The sawdust can easily be obtained by rasping the wood with a suitable wood rasp. The apparatus used for the purpose in this laboratory consists of two wood rasps fastened

to a support to which a water motor gives a reciprocating horizontal movement of about 6 inches on full stroke. The wood is held in a jacket and pressed down on the wood rasps by means of lead weights. The sawdust drops into a box below.

Since Schorger* found that the final cellulose residue still contained fragments of wood that were only partially reduced, and therefore gave a strong methoxy reaction, it is not surprising that his values for cellulose were extremely high and that great variations in the results were experienced. This could no doubt have been avoided by using a more uniform material. Referring to Heuser and Sieber's investigation, mentioned above, the authors are unable to agree with Schorger when he says that "in obtaining the cellulose absolutely free from lignin the error involved by destruction of the cellulose is out of all proportion to that caused by the presence of small quantities of lignin."

Variations in the results obtained by the chlorination method may be partly due to the mechanical handling of the material during the process of purification. According to the original method the fibrous material was transferred from chlorination flask to crucible and *vice versa* several times, which involved a possibility of fibre losses even with very careful handling. Schorger and Renker used this method of operation. Dean and Tower† were the first to propose that the fibres be left in the same container during the entire operation, and the arrangement suggested by Sieber and Walter, which is based upon this principle, is a great step towards the perfection of the method. As in recent investigations use has not been made of this improvement, which is in our opinion extremely valuable, the preparation of the Gooch crucible as suggested by Sieber and Walter is described here. A perforated porcelain plate, A (see fig.), which fits well to the bottom of the Gooch crucible, is sewn with cotton thread between two pieces of fine bleached calico cloth, B, and the projecting parts cut off close to the edge of the plate. After the plate has been purified by boiling with alcohol and water it is fastened in

the bottom of the crucible with a fine platinum wire, C. It is often necessary, owing to uneven plates, to place a little absorbent cotton between the plate and the crucible bottom. The crucible is then dried at 105° C. to constant weight and weighed in a weighing bottle. By the use of this crucible, in which the fibrous material remains during the entire process, very satisfactory results are obtained as regards duplicate work, but the values are very high in comparison with the yields obtained in the commercial cooking processes and also in comparison with other methods.

As all the lignin is removed in the chlorination process this would indicate the presence of other non-cellulose substances in the residue. In fact König and Huhn have strongly criticised this method because the residue, by distillation with hydrochloric acid, yields large amounts of furfural, which can only be removed by hydrolysis. According to König's method and a method proposed by Tollens and Dmochowski,‡ these furfural-yielding impurities can be removed by hydrolysis with inorganic acids and with alkalis which, though effecting a nearly complete removal of these substances, attack the cellulose itself seriously,

making these methods unsuitable for exact analysis. All inorganic acids, even if very dilute, will destroy the cellulose more or less, but this is not true of certain organic acids. It was found that acetic acid in admixture with glycerin, at a high temperature, is able to hydrolyse the lower carbohydrates and a large proportion of the furfural-yielding substances without attacking the cellulose. The mixture was made by mixing glacial acetic acid with glycerin of sp. gr. 1.26 in the proportion of their molecular weights (60 : 92). This mixture can be heated at 135°–140° C. in an open flask, making it possible to carry out the hydrolysis at this high temperature without complicated apparatus. The glycerin causes the fibre substance to swell, whereby the action of the chlorine gas is greatly facilitated. The accompanying curves show that the loss in weight of the wood by treatment with this mixture is at first very rapid, but that after 3–4 hours a maximum

EFFECT OF HYDROLYSIS BY ACETIC ACID & GLYCERINE AT 137° C

is reached. The mixture also dissolves the resin to a great extent, but a treatment with alcohol previous to the hydrolysis is considered to be favourable in order to secure a total removal of the resin and also possibly to effect a dehydration of hydrated cellulose.

The following is the method adopted for the determination of cellulose. Two samples of about one gram each of air-dry sawdust, passing an 80-mesh but not a 100-mesh sieve, are weighed exactly, transferred to small flasks, and heated on a water bath for $\frac{1}{2}$ hour with alcohol, filtered into the crucibles, and washed with hot alcohol. The samples are then transferred from the crucible to 150 c.c. flasks and covered with about 75 c.c. of the mixture of glycerin and acetic acid and heated in an oil bath at 135° C. for four hours, using long glass tubes as air condensers. The material is then collected in the crucibles, washed well with hot water, and the crucibles after cooling placed in the chlorination apparatus in which they are connected with the source of chlorine in such a manner as to prevent escape of the gas into the laboratory. The gas is now passed through the crucibles for 20 minutes, after which the free chlorine is removed from the material by washing once with a cold, dilute solution of sulphurous acid in water. The crucibles are then placed in small beakers which are filled not quite to the top of the crucibles with a 3% solution of sodium sulphite and heated in a water bath for $\frac{1}{2}$ hour. The material in each crucible is washed with hot water, using a filtering flask, and after cooling, the chlorination process is repeated in the same

way three times, the periods of chlorination being first 15, then 15, and finally 10 minutes. After the last treatment with sodium sulphite the fibres, after being thoroughly washed, are dried at 105° C. for four hours or to constant weight and weighed in closed weighing bottles. The residues are calculated in percentage of bone-dry wood, the moisture of the original sawdust having been determined in a separate sample by drying about two grams of the material for four hours at 105° C.

Table I gives a comparison of the cellulose content of a few Canadian wood species as determined by this modified method and by the original chlorination method (without acid hydrolysis).

TABLE I.—Cellulose content of some Canadian woods.

Species.	Diam. ins.	Annual rings.	Cellulose %.	
			Original method.	Modified method.
Aspen (<i>Populus tremuloides</i>)	11½	38	60.95 60.95	57.35 57.15
Black spruce (<i>Picea mariana</i>)	9½	74	54.55 54.60	50.78 50.50
Red spruce (<i>Picea rubens</i>)	10½	60	54.95 55.10	52.95 52.95
White spruce (<i>Picea canadensis</i>)	10½	83	60.66 59.95	56.55 56.40
Jack pine (<i>Pinus banksiana</i>)	8½	61	53.08 53.20	49.35 49.13
Balsam fir (<i>Abies balsamea</i>)	6½	54	54.45 54.40	51.50 51.70
Hemlock (<i>Tsuga canadensis</i>)	12½	119	48.68 48.72	

The figures show that the cellulose values obtained by the modified method are from 2 to 4% lower than those obtained by the original chlorination method. The hydrolysis has consequently removed certain substances which are not removed by the latter method. As the chief non-cellulose substances in the wood, other than resins, are known as lignin and furfural-yielding substances, the yield of methyl groups by distillation with hydriodic acid and the yield of furfural by distillation with hydrochloric acid and precipitation with phloroglucinol were determined in the residues obtained by treating balsam fir and aspen according to the two methods.

TABLE II.—Comparison of the residues obtained by the two methods.

Residue from—	Method.	Furfural.	Methylfurfural.	Total furfural.	Methyl (CH ₃).
		%	%	%	%
Balsam fir	Original	3.87	1.56	5.43	0.1399
"	Modified	2.95	1.43	4.38	0.1392
Aspen	Original	10.49	1.39	11.88	0.135
"	Modified	8.73	1.43	10.16	0.127

The residues give no colour reaction for lignin and are completely soluble in concentrated sulphuric acid giving a colourless solution. A low yield of methyl is still obtained. This methyl reaction is characteristic for the bleached commercial wood pulps, which are generally recognised as the purest form of wood pulps. The reaction is of the same strength and must originate from the presence of very small quantities of an undefined highly resistant substance. The furfural values show a very noticeable difference in favour of the modified method and it is interesting to note the similarity of the residue to the high grade commercial pulps with regard to furfural yield. It was not possible to secure a sample of commercial bleached sulphite pulp from balsam fir alone, but a bleached sulphite pulp from spruce

in mixture with a small percentage of balsam fir gave 3.10% furfural and may be used for comparison, as the difference of the two species with regard to furfural yield is not very appreciable. A soda pulp from aspen wood gave 9.69% furfural. These values are very close to those found for the cellulose residues obtained by the modified method. It would, of course, not be correct to judge the value of a method for cellulose determinations from the similarity of the residue to the commercial pulps, but this similarity of products obtained with different materials by different methods indicates that there is a certain amount of a very resistant substance in the wood which may be considered as the ultimate product of the commercial processes of purification. As an identical substance is obtained in the modified method of cellulose determination, it may be considered very useful in the valuation of the various woods for the commercial paper pulp processes.

Interesting differences in the distribution of the cellulose throughout the tree can be detected. On a previous occasion* the decrease in cellulose content from the base towards the top of the tree was reported. The cellulose content was also determined at the same height from the ground at various distances from the pith of the tree towards the bark. The following figures were obtained from a disc of balsam fir with 64 annual rings and a diameter of 10½ inches:—

TABLE III.—Variation in cellulose content in balsam fir from pith to bark.

Cellulose %.		
A.	B.	C.
51.98 51.20	53.25 53.28	54.27 54.15

A.—Includes sample from pith to 15th annual ring. B.—From 20th to 35th annual ring. C.—Sap wood (outer 15 rings).

From a disc of aspen 9½ inches in diameter and 80 annual rings the cellulose content of sapwood and heartwood was compared.

TABLE IV.—Cellulose content of aspen.

Sap.	Heart.
%	%
61.24 61.45	59.88 60.19

In both species the sapwood has a higher cellulose content than the heartwood, and from the former table it may be taken that there is an appreciable variation in the cellulose content throughout the heartwood, at least in trees grown under normal conditions. But the growth of a

* Pulp and Paper Mag., 1917, 15, 333.

tree is very much dependent upon the position and upon the growth conditions determined by its surroundings. In fact, it is seldom that a tree of absolute normal growth is found.

A disc was also taken from a balsam fir tree with a great proportion of "rotholz" (a condition due to strain or climate during the period of formation). One part of the disc showed very rapid growth and another part slow and normal growth. The disc had an average diameter of 9 inches and contained 51 annual rings. The differences in cellulose content were so considerable in the various parts of this disc that for comparison the lignin content was determined by treating the fibres with 72% sulphuric acid in the cold for a period of three hours. The yield of methyl by distillation with hydriodic acid and the solubility in alcohol were also determined.

TABLE V.—Analysis of disc of balsam fir of abnormal growth.

	" Rotholz."	Rapid growth.	Slow growth.
Cellulose, %	39.42	50.35	52.85
Soluble in alcohol, %	1.38	2.05	2.85
Lignin, %	33.6	24.44	24.85
Methyl (CH ₃), %	2.74	2.43	2.62

Even after many years of normal growth, trees may gradually lose their value both for structural purposes and as paper-making material as the result of attack of wood-destroying fungi. Vast areas of forest are often covered with trees so seriously damaged by fungous growth that they have not yet been used as a raw material in any industry, and their utilisation is a great problem to the forester. The fungus *Fomes igniarius* (false tinder fungus) is distributed practically all over the world. Starting from a wound in the tree it extends its path of destruction over the entire heartwood, rendering the wood entirely useless for structural purposes.

According to von Schrenk and Spaulding* one of the principal effects of the fungus *Fomes igniarius* is the solution of the lignin elements of the cell wall. But an analysis of a typical sample of aspen attacked by this fungus did not confirm this statement. Samples from the decayed heartwood and from the sound part were analysed with the result shown in Table VI.

TABLE VI.—Analysis of aspen attacked by the fungus *Fomes igniarius*.

Material.	Diameter.	Cellulose.	Furfural.	Methylfurfural.	Total furfural.	Lignin.	Soluble in hot water.
Sound wood	ins.	%	%	%	%	%	%
Decayed wood	101	58.80	10.52	1.64	12.16	7.86	4.0
	—	42.20	9.98	2.10	12.08	13.16	14.85

This table distinctly shows, contrary to the claim of von Schrenk and Spaulding, that the cellulose has been broken down, and it further shows that the furfural-yielding substances are also attacked. The copper numbers (1.99 for the sound part and 8.05 for the decayed wood), and the solubility in boiling water also show that the cellulose has been broken down into reducing substances, presumably sugars.

These few examples of the application of the modified method of cellulose determination may be sufficient to demonstrate its usefulness in the analysis of wood, especially in relation to the production of chemical wood pulp.

The results recorded below were obtained in an

investigation of the action of the various reagents employed in the method of cellulose determination upon the most important constituents of the wood. This work was undertaken in order to secure as much information as possible regarding the details of the method of purification and to obtain, if possible, new data regarding the general composition of wood.

In discussing the determination of cellulose, reference was made to the other quantitatively most important substances in the wood, namely, lignin, the substances yielding furfural, and the other carbohydrates of comparatively low molecular weight. The characteristic reactions of these substances have been used in determining their presence in the original wood as well as in the residues isolated from this. These reactions were also used in studying quantitatively the nature of the substances which are removed by the various reagents employed in separating the cellulose residue from aspen and balsam fir. Samples of these species were disintegrated by means of a rasp and the material which passed the 80-mesh sieve but not the 100-mesh sieve was used for analysis. The material was extracted by boiling first with ether for 6 hours and afterwards with alcohol for 6 hours under a reflux condenser and with continuous stirring in each case. The extracted wood was then boiled in water for 6 hours under a reflux condenser with constant agitation and the material afterwards washed with hot water and then air-dried.

1. Small samples of the original wood were treated in exactly the same manner and dried at 105° C. and the loss in weight determined. The extracted and air-dried wood served as material for the tests recorded below. The tests were as follows:—

2. One part of the extracted wood was heated, in a beaker placed in a boiling water bath, for 4 hours, with a 3% solution of sodium sulphite and the fibres afterwards collected on a filter, washed with hot water, and air-dried.

3. Another part was heated with the mixture of acetic acid and glycerin in a flask under a reflux condenser at 135° C., using an oil bath. The residue was then washed on a filter with hot water and air-dried.

4. Another sample was treated according to the original method of chlorination and the cellulose residue, after thorough washing with hot water, was air-dried.

5. One sample was treated according to the modified method of cellulose determination, the residue being thoroughly washed with hot water and afterwards air-dried.

The loss in weight by each treatment was determined in separate samples and calculated upon the bone-dry weight of original wood. With all the residues the following analyses were made:—The yield of furfural and methylfurfural was determined by distillation with hydrochloric acid and precipitation with phloroglucinol according to the Tollens and Kroeber* method, and extraction of methylfurfural with alcohol according to Ellet and Tollens.† Lignin was determined by treating the fibre for three hours with cold 72% sulphuric

acid, the residue being considered as lignin according to Klason.* Methyl groups were determined by distillation with hydriodic acid as proposed by Benedict and Bamberger.†

typical reaction. It must, however, be remembered that the furfural reaction is by no means a characteristic reaction for oxycellulose since, for instance, the typical oxycellulose

* The 100% as given in this table refers to the lignin test with 72% sulphuric acid, which gives no residue or colour reaction when used on the cellulose residue.

From the figures contained in these tables it is again seen that there are striking differences in the chemical composition of balsam fir and aspen or, in general, between the coniferous woods and the broad-leaved woods. The differences may be briefly summarised as follows:—The broad-leaved trees give a considerably higher yield of furfural than the coniferous woods, which latter contain much more substance yielding methylfurfural. This substance, or at least part of it, is apparently very resistant, as there always remains a considerable proportion of it in the residue. The commercial pulps likewise contain a large proportion of this substance, and it is interesting to note the high resistance of the substance yielding methylfurfural in the analysis of decayed aspen given in the previous part of this paper.

The action of the various reagents in the different treatments used is to remove the complex yielding furfural and methylfurfural; the quantities thus removed depend upon the hydrolysing effect of the reagent employed, the effect of the acetic acid treatment being most pronounced.

In the tables given above the yield of furfural is also calculated as pentosan, the formation of furfural being a typical reaction for pentosans. Other substances have also been shown to be responsible for the furfural yield.

Cross and Bevan, who have classified wood as lignocellulose, claim that the cellulose residues they obtain from wood are not true celluloses of the same type as cotton cellulose but that they are, in properties, true oxycelluloses, giving furfural as a

obtained by treatment with calcium hypochlorite solution does not give the reaction. Moreover these cellulose residues do not show the most typical oxycellulose reaction, namely, the high reducing power (copper number). It must also be considered that the substance which gives the furfural yield can be partly removed by a strong acid treatment, according to König*, although not without a simultaneous destruction of the cellulose. Furfural is also obtained from "wood gum," a substance which can be extracted from the broad-leaved woods in large quantities (about 15%), and from coniferous woods only in very small quantities by treatment with cold alkali and precipitating with alcohol. The wood gum in some cases also gives a methoxy reaction. This wood gum cannot be considered a uniform product, but no doubt is a mixture of hydrolysed pentosan and dissolved lignin.

The furfural yield of the cellulose residue has also been traced to so-called furfuroids,† substances which are similar to the pentosans in giving furfural but differ from the pentosans in being fermentable. They are considered to be more resistant than the pentosans and are therefore contained in the isolated cellulose residues of the wood. There is also the possibility that the product is a mixture of various constituents of the wood, that is, chiefly products of hydrolysis of pentosans and hexosans, which would explain the characteristic reactions.

The values for lignin obtained by treatment

with sulphuric acid, and for methyl (which also is considered to be a quantitative lignin reaction) show a very peculiar difference in the two classes of woods and also in the two methods. Aspen with the highest yield of methyl only gives a very low value for lignin with sulphuric acid. There is, therefore, absolutely no connection between these values and the apparent disagreement in the results must be explained by the presence of two very different types of lignin. That there are different types of lignin has been indicated by Klason,* who isolated the barium salt of lignin-sulphonic acid from waste sulphite liquor. While only about one-half of the lignin could be recovered in this way the high yield of methyl from this compound, in comparison with the lignin content of the wood, points to the conclusion that there are at least two lignins in spruce wood, of which one is very low in methoxy groups. Klason was also able to remove from wood, by alternate extraction with alcohol and water, a small proportion of lignin of a comparatively low molecular weight, whereas the barium salt of lignin-sulphonic acid recovered from the waste liquor was found according to him to have a molecular weight above 6000. Langet† isolated from various woods two lignic acids of different composition which varied in their solubility in alcohol. Apparently there are considerable differences in the types of the lignin substances of aspen and of balsam fir which are especially characterised by their solubility in concentrated sulphuric acid. Klason's method of determining lignin by treatment with 72% sulphuric acid is recommended for spruce and can, as far as our experience goes with the Canadian woods, be used with advantage with the coniferous woods in general, but seems to fail entirely with the broad-leaved trees.

The tables given above also show that it has not been possible with any of the reagents to extract only one uniform substance from the wood. A greater or a smaller proportion of a substance may always be dissolved out, but always in admixture with the other non-cellulose constituents. This has been stated on many occasions and has been explained by a difference in resistance of the various modifications of each substance. In this way designations such as hemi-celluloses, pseudo-celluloses, hemi-lignins, etc., have been proposed. König and Rumpf‡ have classified the non-cellulose substance of the cell membranes according to their resistances towards hydrolysis as "proto-pentosans," "proto-hexosans" and "proto-lignins" which are removable with water at 2–4 atmospheres pressure; the "hemi" type of the same substances which are removed by 1–3% acids at 2–4 atmospheres; and the "ortho" types of the substances which can be removed only by strong acid or by dilute acid at high pressure. These examples will be sufficient to show how difficult it is at the present time to form any opinion as to the constitution of wood, but they indicate that besides analytical work a critical study of the literature on wood chemistry is very much needed in order to simplify the terminology of the chemistry of wood.

Wislicenus§ has studied the problem from the point of view of colloid chemistry. He was able to precipitate from the cambium sap of the plant 39% of its dry weight by adsorption on colloidal clay and put forward the theory that the lignin represents colloids separated out from the cambium sap by adsorption, one part of which is reversibly, and another irreversibly deposited on the cellulose. Klason|| favours this opinion

and from his own investigations draws the conclusion that 6% of the total lignin is reversibly combined with the carbohydrates of the wood, namely, the 2% of lignin which he was able to dissolve out merely by boiling with water and with alcohol alternately.

Wislicenus' theory according to which the lignin and the carbohydrates of the wood are combined on the basis of the force of the surface tension, and therefore in varying proportions, can no doubt be applied to the other substances of the wood, and will probably form the basis for future investigations in the chemistry of wood. The great similarity of the woods with regard to chemical composition and the fact that it is not possible to dissolve out any of the chief constituents without attacking the other substances, makes it probable that each of the substances cellulose, lignin, pentosans, and hexosans, are present in the wood, partly in a free form and partly more or less closely attached to the other substances, which explains the uniformity in the composition of each species. This equilibrium, however, must change as soon as one or more substances are changed in quantity or are totally absent. If we consider the high percentage of pentosans and the difference in the nature of the lower polysaccharides of the broad-leaved woods in comparison with the coniferous woods, it may be possible to explain the difference in behaviour of the lignin complex of the two classes of woods towards chemical reagents (hydrolysis) and also the apparently close attachment of the pentosans to the cellulose in the case of aspen.

This point of view does not, of course, exclude the probability that the lignin groups as well as the groups of pentosans and hexosans may consist of compounds of the same composition, but with varying molecular weights.

THE PRESERVATION OF DECAYING STONE.

BY A. P. LAURIE, M.A., D.SC., AND CLERK RANKEN, D.SC.

(Abstract.)

This enquiry has been undertaken at the request of His Majesty's Office of Works with a view to dealing with the pressing problem of the preservation of decaying stonework in ancient buildings, and the following observations are the results of the preliminary experiments. It is therefore not merely a question of treating a stone which is at present free from decay, with some solution which will increase its durability. In the case of these ancient buildings the stone is already decayed to a certain extent and is in a crumbling condition. If this crumbling surface is cleaned off, the whole artistic value of the work is destroyed. It is therefore necessary to find something which will not only preserve the stone from further decay, but will reconstruct the existing crumbling stone.

Various substances have been put on the market with a view to stone preservation. These substances can be classified into certain groups. Some of them consist of materials of the nature of paraffin

* "Beiträge zur Kenntniss der chem. Zusammensetzung des Fichtenholzes," Berlin, p. 12.

wax dissolved in a volatile solvent, the idea being to fill the pores of the stone with a neutral substance which will prevent further admission of moisture and will tend to bind the particles together. Others consist of solutions of materials like linseed oil, which are gradually converted by the action of oxygen into jellies, which are meant to fill the particles of the stone.

There are others which are intended to act upon the calcium carbonate or sulphate, producing insoluble compounds which are intended to bind the stone together. And there are others in which two solutions are used, with a view to form a precipitate within the pores of the stone itself.

In the case of the simplest form of preservative—a solution of a solid which is to be left in the stone on evaporation, like paraffin wax—the difficulty is to ensure that the solid will be left within the interior of the stone, the probability being that in most cases—as a result of capillary action—it will be found in the outer layer. This also probably applies to solutions which are intended to decompose spontaneously, as they will be drawn out by evaporation before decomposition takes place.

Better results might be hoped for in the case of solutions which are intended to act on calcite or calcium sulphate already within the stone, and so produce an insoluble precipitate, though, on the other hand, they involve serious questions as to how far it is wise to attack an existing cementing material with a view of forming a new one.

In practice, it has been noticed that in many cases preservatives, while producing temporary effect, ultimately result in scaling.

The result of our experiments is to show that, even if a stone is sprayed several times with solutions of paraffin wax, it will not be rendered non-porous to moisture. It would be necessary to carry on the loading with paraffin wax to a point which would be quite impossible in practice, in order to obtain this result. But it has also been found that the paraffin wax has a marked effect on the process of evaporation which takes place afterwards. If the stone has been sprayed with paraffin wax before treatment with a potassium ferrocyanide solution, this spraying will only partially prevent the absorption of the solution, but tends to prevent on evaporation the crystallisation of the potassium ferrocyanide on the outside of the stone. The tendency, however, for such crystallisation is to take place principally just underneath the paraffin wax layer. This layer is very thin, the solution of paraffin wax being absorbed readily by the stone, but on evaporation depositing the paraffin wax at, or near, the surface. It is evident, therefore, that a stone so treated with paraffin wax will still continue to absorb moisture, while the resulting products of decomposition will tend to collect just under the surface layer, and by crystallising out in that position, will ultimately produce flaking of the stone.

It is probable, therefore, that all stone preservatives of a greasy nature will be peculiarly apt to produce flaking ultimately on the stone. This raises the interesting question how far the deposit of greasy smoke particles is an important agent in the decay of stone.

It is obvious then that the first problem is to ensure that the particular material used permanently penetrates to a considerable depth within the stone itself, the first penetration being of no value, owing to the subsequent evaporation.

Phenomena involved in the use of two precipitating solutions.

If a piece of stone about 1 in. in section was saturated with one solution and then poulticed on one side with another solution that would form a precipitate, we found in some cases that there

was not only a copious precipitate on the side of the stone that was poulticed, but a so a copious precipitate on the back of the stone, penetrating a little way into the interior; while in the centre of the stone, very little, if any, precipitation was visible.

The cementing properties of precipitates.

If the pores of the stone have been filled to a sufficient depth with an insoluble substance, are we justified in assuming that this substance will form a successful binding material, holding the particles of the stone together?

A large number of organic substances, such as linseed oil, paraffin wax, casein, resins, and gums, have the property of cementing particles together, and we also know from the study of stones themselves, that many substances also will act as a cement, even a crystalline body such as calcite forming a firm and strong cement between particles of quartz.

We are also familiar with the cementing properties of the jelloids produced during the setting of Portland cement, but in the case of stones, these inorganic cements have been produced very slowly and under special conditions, while in the case of Portland cement, the partial change into a gelatinous mass with the minimum quantity of water present is very different from the conditions of precipitation when a stone is treated in the usual way with two precipitating substances.

We are therefore not justified in assuming that even such substances as silica or alumina are going to act as a cementing material of any value when precipitated rapidly within the pores of the stone.

We decided in the first place to study what happens when a stone is treated with a simple solution whether of a salt in water or of a material like paraffin wax dissolved in a volatile solvent.

A large number of slabs, about 4 in. each way and about 1 in. thick, were cut from Cullaloe stone, a fairly porous stone, consisting almost entirely of silica, the analysis being as follows:—Silicious matter 99.17%, Al_2O_3 0.11%, Fe_2O_3 0.07%, $MgCO_3$ 0.12%, combined water, etc. 0.46%, moisture 0.03%. The binding material between the particles of quartz is apparently a silicious deposit. This stone was therefore selected as not being likely to introduce any chemical complications in the experiments.

A series of wooden frames were made, with a flange, similar to picture frames, into which the slabs of stone could be fitted, and pressed up against a rubber washer, by means of clamps. In this way one surface of the stone was exposed, and could be treated by spraying with various materials, while at the same time, the creeping of the solution round the edges of the stone was prevented by the rubber washer. In addition to spraying, we ultimately adopted, as a much more effective method, covering the surface with paper pulp soaked with the solution with which we wished to treat the stone, and covering the paper pulp again with lead foil, the whole being pressed gently against the stone, so as to remain in contact. Such solutions laid on in this way would remain moist for some time, and if necessary could be renewed from time to time.

We also had a small machine constructed, consisting of a cylinder and a screw piston, for compressing and forming small cylindrical bricks, in order to test the behaviour of various solutions when mixed with pure white sand, ground Portland stone, and ground Ketton stone, as representatives of pure silicious sandstone, calcareous sandstone, and purely calcareous stone. By mixing these powders with various solutions, precipitates, and preservatives, and pressing them into bricks, it was possible to test, under very advantageous

circumstances to the solutions used, how these solutions behaved, and to what extent they could be regarded as successful binding materials.

The first experiments were made to test the question as to how far, after treatment with the solution, capillary forces came into play, and removed the solution from the stone.

Some of the slabs of stone already described, after having been mounted in the wooden frames, were treated with the following salts in solution in water:—Potassium ferrocyanide, sodium phosphate, sodium sulphate, ammonium phosphate, copper sulphate, copper nitrate, lead nitrate, copper chloride, potassium chromate, potassium arsenite, potassium bichromate, cobalt chloride, ferric chloride, barium acetate, chromium chloride, soap. The reason for the selection of these salts was that in most instances they lend themselves to detection by means of strong colouring actions.

With the exception of ferric and chromium chloride, soap, and potassium arsenite, in every instance it was found that as the stone dried the salt in solution was practically removed almost entirely to the surface layer, although before the stone was allowed to dry it had been saturated with the solution, which had begun to crystallise on the back of the stone.

The tendency, however, to rush rapidly out from the stone is not equally strong in the case of all these salts, potassium ferrocyanide being the most marked example of the kind.

Three salts, ferric and chromic chloride and potassium arsenite, and also soap, were found to be exceptions to the general rule, these salts remaining to a very large extent within the interior of the stone.

In order to test organic substances, we selected solutions of shellac in alcohol, and of paraffin wax in xylol, and, as has already been stated, we not only found that several sprayings of paraffin wax were not sufficient to make a stone really water-tight, but we also found that both these substances came to the surface of the stone during the process of drying. We also found that if the stone was first lightly sprayed with a solution of paraffin wax in xylol, and then treated with a salt solution, there was very much less tendency for the salt to crystallise on the outside of the stone and that the distribution in the interior of the stone was better, but that there was a distinct tendency for an excess of the salt to be deposited just underneath the main paraffin wax layer, which lay from 1/16th to 1/8th of an inch below the surface of the stone. This result has already been referred to, as showing the danger of using greasy materials as stone preservatives, in that it tends to cause an accumulation of crystalline matter dissolved from the stone, just under the surface layer.

In order to check these experiments, we made a series of experiments with the bricks made of sand, with a view to finding out how the solution would be distributed under those conditions. In each case, of course, the solution was mixed evenly throughout the sand. The little brick was then allowed to dry, and examined; it was then, in many cases, immersed in water, to see what would happen under those conditions. Solutions of shellac, gelatin, paraffin wax, and albumin, were all tried, and in each case the result was formation on the outside of the brick—which was about 1 in. in diameter and about 2 in. long—of a hard layer about 1/16th of an inch thick, while if a hole was drilled inside the brick, the sand could be poured freely from the interior.

Some experiments, however, made with gelatin require to be discussed in more detail, as they illustrate a very interesting point in this connection. If a stone is treated with a liquid which solidifies without evaporation, the liquid should remain throughout the stone evenly distributed. That this is so was shown by experiments with bricks

made with solutions of gelatin in water. In the case of a 1% solution the hardening was entirely superficial, the sand pouring freely from the interior; this was still true, but to a lesser extent, for the 3% solution; but in the case of the 5% solution the hardening of the sand brick took place all through.

While, in the case of these inorganic solutions which we have tested, with the exception of ferric and chromic chloride and potassium arsenite, the result has been to bring the solid to the surface, there are no doubt exceptions to this rule, as it is possible to select substances which, when dissolved in water, lower the surface tension instead of increasing it, such as a solution of soap; and, moreover, as the surface tension of a mixture is the sum of the surface tension of the separate constituents, it is quite possible that the tendency of one substance in solution to cause crystallisation on the outside of the stone might be counteracted by the condition of another substance. Investigation in this direction was carried out, and the effects of sugar, glycerin, starch, and soap were tried on aqueous solutions of various salts.

(1) Glycerin on every occasion was found to favour retention. Even with saturated potassium ferrocyanide only a very small amount crystallised on the surface.

(2) Soap produced practically no effect.

(3) Starch caused retention to a small extent but, on the other hand, did not permit of the stone taking up the solution readily.

(4) Glucose caused retention better than starch, but not nearly so great as glycerin.

Method of experiment.

(A) Stones soaked with concentrated solutions of potassium ferrocyanide, copper chloride, or barium chloride and allowed to dry gave large crops of crystals on the surface after 2 or 3 days.

(B) Stones soaked with the same concentrated solutions to which a small amount of glycerin, etc., had been added and allowed to dry, were compared with (A). Also after standing drying for 3 weeks, the stones (B) were broken and the interior tested. The tests showed whether the stones did or did not retain; e.g., a Cellulose sandstone slab treated with concentrated potassium ferrocyanide and a drop or two of glycerin was allowed to dry for 3 weeks, broken and the surface and the interior tested with drops of ferric chloride. The Prussian blue formed in the interior was as dense as that on the surface. Again, after drying for 9 months, the ferric chloride test still showed that the potassium ferrocyanide remained in the interior. It was also noticed that the stone had not got absolutely dry after 9 months, but still retained traces of moisture.

The effects of glucose and glycerin, nitrobenzene, aniline, methyl acetate, and ethyl benzoate on retention of alcoholic solutions were also tried. In all cases the addition of glycerin, etc., seemed to have no effect in causing the substances to remain inside the stone.

The result of these experiments is to show that while no reagent has been found to prevent the deposition in the outer layer of substances in organic solvents, the addition of a little glycerin to water solutions is sufficient to prevent this. We therefore recommend that in any practical tests of water dissolved stone preservatives, the precaution of adding a little glycerin be taken.

In order to test how far various substances acted as cements, we made up a series of bricks mixed with various materials, directing special attention to the fluosilicates, as much attention has been directed to them lately as stone preservatives, more especially in Germany.

In the first place, we selected certain gelatinous precipitates which are generally supposed to act as cements, and having made up bricks mixed

with sand and gelatinous precipitates and given them three weeks to dry, we examined their condition and then immersed them in water and examined their condition again. We found that precipitates of alumina and silica completely failed to act as cementing materials in the case of sand. If mixed with a little lime, the bricks were a little harder, but at once got soft in water. Aluminium fluosilicate showed a distinct tendency to come to the surface of the brick, and, whether alone or mixed with lime, the resulting brick was at once softened in water. Zinc hydroxide and calcium hydroxide, alumina and barium hydroxide, stannic acid, and stannic acid and calcium hydroxide, etc., failed to produce bricks which would stand the test of water; while casein, and zinc hydroxide mixed with calcium hydroxide stood the water test successfully.

The results obtained will be found in the following table.

Sand.	Binding material.	Hardness after three weeks.	Hardness in water.
	Alumina	Crumbly.	Very soft.
	Silica hydrated.	Crumbly.	Very soft.
	Alumina + calcium hydroxide	Not quite so crumbly.	Soft.
	Silica hydrated + calcium hydroxide		Soft.
	Aluminium fluosilicate + calcium hydroxide	Harder.	Soft.
	Aluminium fluosilicate	Hard outside.	Very soft.
	Aluminium sulphate then barium hydroxide	Hard outside.	Very soft.
	Zinc hydroxide	Fairly hard.	Soft.
	Zinc hydroxide + calcium hydroxide	Harder.	Hardish.
	Stannic acid	Powder.	—
	Stannic acid + calcium hydroxide	Crumbly.	Very soft.
	Casein	Hard.	Hardish.

We next made up a similar set of bricks with Ketton stone. In this case, zinc fluosilicate, magnesium fluosilicate, and what is known as "Doppel" fluosilicate, as supplied by Hans Hauenschild, Berlin, failed to form permanent bricks. In each case the bricks were crumbly after two weeks, though those prepared with the Doppel fluosilicate were not quite so crumbly as the others.

These results are of considerable importance, as it is claimed for these fluosilicates that in the case of calcareous sandstones, the resulting complex precipitate of fluosilicate of lime and zinc and magnesium hydroxides forms a reliable cementing material.

Any supposed preservative which depends for its success as a binding material on attacking the calcite which the stone contains should be regarded with profound suspicion. The results do not justify the use of a solution which is to depend upon its success in attacking the calcite existing within the stone, destroying the natural cement of the stone, in order to create another. If a solution is to be selected with this aim in view, it is difficult to imagine anything better than the fluosilicates, and it is for that reason that we have tested them so carefully, and have come to the conclusion that they are not reliable.

Such a process must be distinguished from that of Sir Arthur Church, in which case he is attacking the sulphate of lime in the stone, which is already a decomposition product, and therefore is not injuring the structure of the stone by the treatment to which it has been subjected.

The second conclusion which we have arrived at from these experiments is that a very large number of colloid precipitates, such as silica and alumina, cannot be regarded as cementing materials.

The direction, therefore, that the enquiry should take should be, if possible, to find an inorganic substance which is insoluble in rain water and the acids usually found in rain water, which, without requiring to attack in any way the natural combining material of the stone, will form a successful cement for particles of quartz.

The conditions of precipitation within the stone.

It is evident, from what has been already stated, that we have to look for our successful preservative in one of two directions, *i.e.*, we must either find a single solution or liquid which will solidify within the stone and form a successful combining material without showing any tendency to come to the surface, or we must obtain the result by a process of double precipitation, by the action of one solution upon another. The difficulties of obtaining such a solution are sufficiently obvious, but it must not be ruled out of the ultimate possibilities. At the same time, it is very likely that the right method is to use a double solution, and therefore experiments on the precipitation within the stone itself require to be undertaken.

In order to test this question, we decided again to select precipitates, in the first instance, which, on account of their colour, would be fairly visible on the stone, without any reference to their suitability as stone preservatives, in order to get some guiding principles in the matter of such a precipitation.

The main difficulty of successful precipitation in the interior lies in the fact that the first precipitation will take place across the mouths of the capillaries, forming a diaphragm which will be more or less impervious to the passage of the salt molecules in either direction. At the same time we might expect to find the molecules of one of the salts might penetrate very much more easily than the molecules of the other, and therefore that the order in which the treatment of the stone took place would prove of considerable importance.

In most of these experiments we did not allow the stone to dry completely before applying the second solution; in some cases applying the the second solution directly, before evaporation could have taken place; in other cases allowing partial drying before its application. We also in certain cases sprayed the stone lightly with paraffin wax on both surfaces, so as to tend to keep the first solution within the stone and give the precipitation a better opportunity.

The experiments on spraying the unwaxed stone showed that in every case the precipitation took place on the surface layer of the stone, and there was no proper penetration. The only successful experiments have been those made by means of the poulticing method, which has already been described. These results show that it depends very largely upon which salt solution is applied first, a fair precipitate being obtained inside in certain cases, while, when the treatment with the salts is reversed, practically no precipitation takes place at all. One of the necessary conditions, therefore, of success is to decide in which order the solutions are to be applied. It was decided to test the use of two different solvents for the salts. The idea of these experiments was to select two salts, which will result when mixed in a precipitate, one soluble in water and alcohol, the other insoluble in alcohol. If the stone is first treated with the water solution and allowed to dry leaving the salt precipitated throughout it, and if it is then treated with the second salt dissolved in alcohol, the second salt will be able to penetrate freely into the pores, owing to the fact that the precipitation will be delayed owing to the insolubility of the first salt in alcohol, and therefore we may hope to get the precipitation taking place within the stone.

Further experiments on precipitation of substances inside stone.

Further experiments in this direction lead to the conclusion that the decisive factor in precipitation in the stone is the order in which the stone is treated with the solutions causing precipitation. Practically perfect precipitation was produced in the stone when potassium ferrocyanide was the second solution used, whereas when it was the first solution there was practically no precipitation in the stone.

The use of different solvents has certain advantages in so far that no waiting is required between treatment with the two different solutions. Waiting, however, is no real disadvantage owing to glycerin, etc. being able to keep the first substance in the interior of the stone.

the precipitation of one solution by another—must be a material which is not readily attacked by air, water, or the acids usually present in rain water.

(3) None of the solutions used should act upon the natural cementing material of the stone, or should depend upon that action in order to produce a binding material.

(4) The resulting solid—whether produced from one or from two solutions—must be one which has been proved by severe tests to act as a cement for particles of silica.

(5) If two solutions are to be used it is very important to study carefully the right order of application in order to ensure proper penetration, or to use two different solvents in the way already described.

Stone.	Treated first with :	Drying period.	Treated with :	Result.
Waxed	Lead nitrate (aqueous saturated) until crystals at back.	1 day	Potassium chromate (saturated) for 6 days.	Practically no precipitate inside. All round outside. 1.1th inch.
Unwaxed	Borax.	3 days	Copper sulphate (saturated).	No precipitate inside. All round outside.
Unwaxed	Lead nitrate (aqueous saturated) until crystals at back.	1 day	Potassium chromate (saturated) for 6 days.	No precipitate inside. All outside. 1/16th inch.
Unwaxed	Potassium chromate (saturated) until crystals at back.	1 day	Lead nitrate (saturated) for 6 days.	Fair precipitate inside stone (irregular).
Waxed	Potassium chromate (saturated) until crystals at back.	1 day	Lead nitrate (saturated) for 6 days.	Fair precipitate inside stone (irregular).
Unwaxed	Copper sulphate (saturated).	1 day	Potassium ferrocyanide for 6 days.	Small amount of precipitate in layers in stone.
Waxed	Copper sulphate (saturated).	1 day	Potassium ferrocyanide for 6 days.	Precipitate going through stone in layers.
Unwaxed	Potassium chromate.	1 day	Lead nitrate.	No precipitate in stone.
Unwaxed	Copper nitrate.	3 hours and then waxed	Potassium ferrocyanide.	Little or no precipitate in stone. It penetrated but only gave streaks.
Unwaxed	Copper sulphate (aqueous).	None	Alcoholic caustic potash for 2 days.	Black copper oxide well through stone.
Unwaxed	Caustic potash (alcoholic).	2 hours	Aqueous copper nitrate.	No precipitate in stone.
Unwaxed	Copper chloride (alcoholic).	None	Aqueous sodium sulphide.	Poor precipitate of copper sulphide in stone.
Unwaxed	Sodium sulphide (aqueous).	None	Alcoholic copper chloride.	Very good precipitate in stone.
Unwaxed	Ferric chloride (alcoholic).	None	Aqueous potassium ferrocyanide.	Very fine precipitate in stone.
Unwaxed	Potassium ferrocyanide (aqueous)	None	Alcoholic ferric chloride.	Very poor precipitate in stone.

The result, then, of these experiments on precipitation is to show that, in the first place, methods of spraying with two solutions in water seem to be very unlikely to yield satisfactory results; and that some method of poulticing is apparently essential for success, so as to ensure deep penetration of the solutions. In the second place, if prevention of the salt crystallising on the outside can be obtained, it is possible to get a fairly uniform precipitation within the stone. And, in the third place, even where salts are used which tend to crystallise on the outside, the use of the two solvents results in a very uniform precipitation if the stone is not allowed to dry between the two treatments.

While we do not pretend for a moment that these results can be regarded as more than preliminary, we think that they have been sufficient, in the first place, to show that the problem has not been successfully solved by the existing stone preservatives, and also to show the complex nature of the problem, and the directions in which a solution of it is to be looked for.

These are as follows:—

(1) The solution with which the stone is treated—or if two solutions are to be used, the first solution with which it is treated—must be of such a kind that the resulting solid is uniformly distributed throughout the stone, and does not tend to come to the surface. It must, therefore, be a solution in which the surface tension tends to diminish instead of increase on concentration.

(2) The resulting cement—whether due to the evaporation or solidification of one solution, or to

Yorkshire Section.**THE LOSS OF INDICAN ON DRYING INDIGO LEAF.**

BY E. R. WATSON.

(This Journal, 1918, 81 T.)

DISCUSSION.

Professor A. G. PERKIN said that it was, of course, well known that the indican content of the freshly-gathered indigo plant in its moist condition rapidly deteriorated, but there was no previous record so far as he was aware of the behaviour in this respect of the leaf when dried under ideal conditions. Indeed, it was, and might still be, the case in some parts of India to air-dry the leaf before employing it for the manufacture of indigo, and should only a small amount of colouring principle thus be lost, this procedure would have much to recommend it. As this matter was interesting to him at the time, he had approached Professor Watson, then living in India, and he had very cordially undertaken to carry out the work, an account of which was contained in the paper. It had long been suspected that indigo brown, a well-known impurity of commercial indigo, was derived from indoxyl itself, and thus represented a loss of colouring matter. There was evidence from the work of Rawson and others that this was the case, but unfortunately the matter was difficult to prove with certainty. In

conjunction with Bloxam he had shown that when pure indican was digested with moderately strong hydrochloric acid at the boil, a brown compound termed indoxyl brown was produced in which approximately all the nitrogen originally contained by the glucoside was present. A similar product was also obtained by submitting the leaf extract to the same operation, and in this the whole of the indican should be represented by indoxyl brown. He had recently found that "seeth" water, that is the liquid remaining after the settlement of the indigo, yielded some quantity of a product similar to indigo brown, and he felt that in case during the preparation of a small batch of indigo on the large scale he could obtain samples of the leaf, of the finished indigo, and of the "seeth" water for analysis, a solution of this problem might possibly be arrived at. The results of Professor Watson's experiments now made it evident that an investigation of this character could only be satisfactorily accomplished on the spot.

During his work with Bloxam at the Leeds University some years ago, numerous samples of air-dried indigo leaf obtained for them by the Indian Government had been examined, and it was interesting now to know that the poor indigo-yielding content of many of these, which was approximately 0.6%, did not by any means represent the capacity of the growing material. On the other hand one specimen of *I. sumatrana* leaf had given the surprising amount of 3.13% of indigotin, and it would thus appear that in its fresh condition a considerably larger quantity had been present.

It was interesting to note that the air-dried leaf even enclosed in closely stoppered vessels very gradually suffered alteration, and he had in his possession a sample of this originally rich leaf which when last examined gave but 0.5% of indigotin. The alteration in this case he had ascertained was not due in the main to the formation of indigotin in the leaf substance, but, curiously enough, of indirubin, which was evidence that in these circumstances a portion of the indoxyl was converted into isatin, and then reacted with indoxyl subsequently liberated. A certain amount of brown matter was also formed during this deterioration of the contents of the leaf, but no attempt had yet been made to ascertain its character.

Discussions on Papers.

LIGHTING A CHEMICAL BALANCE.

Mr. H. DROOP RICHMOND writes as follows:—
On page 95 T of the issue of the Journal of March

30th, Mr. B. D. Porritt describes a "Convenient Arrangement for Lighting a Chemical Balance." This arrangement is almost identical with that which has been in use in the Laboratory of Messrs. Boots Pure Drug Co., Ltd., for some years past, which was devised by my predecessor, Mr. T. F. Harvey.

THE ANALYSIS OF ALUMINIUM ALLOYS.

In a contribution to the discussion on the above paper, by B. Collitt and W. Regan (this J. 1918, 91 T), Mr. A. W. WILLIS writes that the estimation of manganese in aluminium alloys may be performed even more simply and expeditiously than described by the authors, as 1 gm. of practically any of the alloys will dissolve readily in 25–30 c.c. of nitric acid of sp. gr. 1.20, if a single drop of hydrofluoric acid be added. This immediately causes much effervescence and rapid solution of the alloy. The solution is then oxidised with bismuthate, cleared and cooled, oxidised cold, and filtered through asbestos as usual. The hydrofluoric acid has no detrimental effect on the results, and enables one to work with a much smaller bulk of solution which is better for the oxidation by bismuthate. For nickel estimation, the glyoxime method gives the most satisfactory results, the process being somewhat simpler than that given in the paper, viz., the alloy is dissolved in dilute hydrochloric acid with the addition of a drop or two of nitric acid to get the copper residue into solution, avoiding excess. Then the solution is diluted and about 10 grms. of tartaric acid added, and when dissolved a suitable quantity of dimethylglyoxime solution, and the liquid made ammoniacal and allowed to stand. It is then filtered through counterpoised papers and the precipitate dried and weighed as usual. The aluminium, copper, etc., are kept in solution by the tartaric acid and ammonia, and the nickel precipitate is quite clean. The manganese and nickel processes as above have been in continuous use in a large works laboratory for some years, and are quite satisfactory for ordinary works purposes. Mr. Grisley's suggested method of titrating the copper with potassium cyanide was tried some three or four years ago and the method found to be quite satisfactory with care, but for rapid works check purposes (mostly performed by junior workers) it was found that the iodide method gave a much better end-point, as the cyanide discharges the copper blue colour somewhat slowly and hence requires slower and more careful titration.

Birmingham Section.

Meeting held at Birmingham University on Thursday,
March 21st, 1918.

MR. L. P. WILSON IN THE CHAIR.

FULMINATE OF MERCURY AND ITS DETERMINATION.

BY G. S. HEAVEN, B.Sc.(LOND.), F.I.C.

Fulminate of mercury was discovered by Howard about 1800, and was described by him in a paper read before the Royal Society. He prepared it by the action of mercuric nitrate on alcohol and also by treating mercury with alcohol in the presence of nitric acid.

Liebig, in 1823, analysed the silver salt and found it to have the same composition as silver cyanate and cyanurate, $\text{HgC}_2\text{N}_2\text{O}_2$.

The constitution of the mercury salt could therefore be represented by either

When fulminate is treated with concentrated hydrochloric acid, it decomposes in accordance with the equation:—

$\text{Hg}(\text{CNO})_2 + 2\text{HCl} + 4\text{H}_2\text{O} = \text{HgCl}_2 + 2\text{NH}_2\text{OH} + 2\text{HCOOH}$
and Schott, in 1891, explained the formation of hydroxylamine and formic acid by attributing to fulminic acid the carbyloxime formula, the addition compound breaking up into formyl chloridoxime:—

Nef (*Annales Chimie et Pharm.*, 1894, 268), described the synthesis of mercury fulminate, by the action of sodium nitromethane on mercuric chloride. This appears to verify the cyclic constitution in view of the formation of the formyl chloridoxime, as above, instead of hydrocyanic acid, when fulminate is treated with hydrochloric acid.

Fulminate is manufactured by a method closely resembling that used in its preparation by Howard. The following is the outline of a published method. A cooled solution of mercuric nitrate, prepared by dissolving 500 grms. of purified mercury in an excess of concentrated nitric acid (4.50 kilos.), is poured into a large flask containing 5 litres of 94% alcohol at a temperature of about 25°C. In about 20 minutes the reaction is complete and the crystals begin to separate. The mixture is poured into a small quantity of water and the fulminate which separates is washed by decantation. It is then sifted through a fine net filter which serves to remove large crystals and finally washed on a finer mesh filter till free from acid.

The fulminate is stored in calico bags under water, and for transportation in bulk the bags containing 20 lb. each are packed in a barrel which is filled with water; this is headed and placed in a large cask likewise filled with water.

The powerful oxidising action of the nitric acid gives rise to various oxidation products such as aldehydes, nitrites, and nitrates. The aldehydes may subsequently reduce the fulminate and give rise to free mercury and to soluble mercurous salts.

For use the fulminate is washed with distilled water, through a sieve of 40-mesh, into a calico bag, the wash water being tested with litmus to ascertain that washing has been complete. Excess of water is then removed by pressure applied either by hand or mechanically, and the fulminate is then dried on fulminate drying cloths in one pound lots or less.

Drying is performed on tables heated either with water or with steam, or on cloths fitted to wooden frames in a current of warm air. The temperature of drying is usually about 63°C., 65°C. being the maximum temperature allowed. The drying fulminate smells of alcohol.

When the fulminate is dry it is cooled to the temperature of the room and the lumps pressed to powder by means of a soft pad, or pressed through the muslin cloths by the hands. The fulminate is then stored in well varnished papier-mâché pots.

The copper tables are attacked by the wet mercury compounds, and the bags on which the fulminate stands, and the copper sieves through which the fulminate passes, become green. Copal varnish has been found to be the best preservative for the tables, and several thicknesses of flannel or of cloth help to keep the mercury fulminate free from copper salts.

Crystalline form. Owing to the smallness of the crystals, which are on the whole microscopic, the fulminate appears to the naked eye as a sparkling powder, more or less fine according to the conditions of manufacture. Personal observations of numerous commercial samples show that the largest of the crystals, or of a repeated series of apparently twinned crystals existing as an individual, does not exceed 1 mm. in length. An average sample, of a coarse make, gave the following results on shaking the dry powder through a series of sieves:—100% passed through an 80-mesh sieve, 40% remained on a 120-mesh sieve, 30% remained on a 200-mesh sieve, and 20% remained on a fine calico. The 10% which passed through the calico could be still further subdivided in size by settling in water, an impalpable powder being finally obtained which under a magnification of 440 diameters showed no crystalline form. Analysis showed it to contain 84% fulminate. This result emphasised the need of thoroughly washing the fulminate.

Another sample gave the following results:—20% remained on a 120-mesh sieve, 30% remained on a 200-mesh sieve, and 30% remained on calico.

It will be seen that even from samples of the same make, there is considerable variation of size which from the point of view of the detonator maker is undesirable.

The colour of commercial samples varies from pale cream to dark brown. Some crystals are colourless and like glass, others have the colouring matter evenly distributed, whilst in others—and this occurs frequently—there is a concentration of colour ranging from a deep pigmented band along an edge to deep spots of colour occurring adventitiously in or on the crystal.

As some manufacturers habitually produce coarse dark powders, and others finer and paler, it might be inferred that the dark coloration of a coarse powder is due to special ingredients, but that there is a definite connection between colour and size of grain in fulminate prepared as described above, is shown by the similarity of coarse powders produced by different makers, as also by the large crystals separated from the bulk of a given sample being darker than the fine. It has been stated that the colour is due to resinous substances, so that the difference may be due either to well-known optical effects or else to the longer contact of large crystals with the mother liquor.

To remove the colour, copper and hydrochloric acid are sometimes added to the reaction

bath, or the fulminate is subsequently bleached in such a mixture. Bleached fulminate is thought to resist moisture when pressed into detonators better than unbleached; this may be due to an alteration of the organic coating which, when damp, tends to reduce the fulminate.

The crystalline form is that of an octahedron; twinning is very common, and takes place in a variety of ways. In each of these ways, successive stages may be traced which form an interesting series. Repeated twinning is also common, and under these conditions the general outline resembles that of the individual crystal, but with serrated edges. Ladderlike forms frequently lead to the clustering round them of crystal fragments forming lumps in the dry powder which give trouble in detonator filling. Crystals with defective outline are found very frequently. Though the substance is very brittle, such outlines cannot be attributed to fracture. Many of them are doubtless due to solution action.

Specific gravity. The specific gravity is given as 4.42, but the gravimetric density is much lower. Gravimetric densities are notably difficult to measure owing to the influence of rate of pouring, tapping, etc., but the following values were obtained by following the same regular procedure:—Very fine pale powder, 1.31; very slightly darker, 1.36; darker and coarser, 1.46; another coarse make, 1.50; darkest and most coarse, 1.57. The size of the crystal has therefore a direct relation also to its gravimetric density. This has an important bearing on the charge plates or scoops used in detonator filling, since equal volumes contain different masses when successive batches of fulminate are used. A graded series of plates is advisable where fine limits of weight of charge have to be worked to.

A series of experiments was made to obtain a relation between gravimetric density and pressure. 1.5 grms. of fulminate was pressed into a cylinder 0.36 inch diameter. In the figure pressures are given in lb. per sq. inch.

The density of fulminate pellets and of detonators in general decreases from the surface downwards, and the degree of crushing follows the same order as the density.

Sensitivity.—The figures given by different authorities for sensitivity vary considerably as the type of apparatus used greatly influences the

figures quoted; relatively valuable results can, however, be obtained from a given apparatus. It is generally considered that coarse powders are more sensitive than fine, though some doubt has been expressed as to the correctness of this opinion. From personal experience I have satisfied myself that there is no room to doubt the fact that large crystals are more sensitive to impact than small ones. But friction tests under certain conditions seem to show that fine crystals are more sensitive.

The following figures were obtained by dropping a 2-oz. weight a distance of 11½ inches. The powder was placed on a hardened and ground steel anvil, and covered with a hardened steel cylinder. One sample of fulminate was taken and the portions separated by sifting.

Coarse powder remaining on a 120-mesh sieve	fired	100
Intermediate, i.e., between 120- and 200-mesh	"	50
Fine, passing fine calico	"	24

Another sample:—

Coarse powder	fired	85
Intermediate	"	45

Very fine powder, washed through calico, failed to fire. The fulminate value of the latter was 86%.

The nature of the surface affects the tests considerably, and the presence of fine mercury smoke makes the fulminate very sensitive.

The behaviour of fulminate under friction tests is remarkable. I have found it very difficult to fire fulminate by friction tests between metal surfaces, although a combination of friction with impact, i.e., glancing blows, will fire the substance. Fulminate composition behaves similarly, although it is far more sensitive to impact test. If the fulminate is wetted and then allowed to dry, it becomes sensitive to friction. These facts may be explained by taking the view that rupture of a cake is necessary. On the other hand, fulminate compositions have been repeatedly fired:—(A) When the composition is spread on well painted surfaces—by rubbing with a cloth rag. (B) On American cloth by brushing with a camel hair brush. (C) On leather, using a camel hair brush. (D) On linoleum by rubbing with rubber or leather instruments. In all these cases the surfaces were non conductive, and I am inclined to attribute the explosions to electrical effects.

The fact that the crystals are crushed in detonators, explains why coarseness of powder does not affect the sensitivity of detonators.

Solubility.—Fulminate is soluble in cold water, put more so in hot, but is also partially decomposed by hot water, yellow basic salts being formed by the hydrolysis. It is soluble in alcohol, ammonia, pyridine, potassium cyanide solution, and with decomposition in alkalis, thiosulphate solution, etc. Sodium thiosulphate is used to destroy waste fulminate, but if the fulminate is in excess, comparatively large individual crystals of fulminate consisting of numerous twinned crystals of fulminate are copiously deposited. Their length is often from 4–5 mm., and they are 1–2 mm. in width. They are generally pyramidal at either end, and it is interesting to note that it is under these conditions that the crystals develop the tabular habit of growth. From saturated solutions in thiosulphate masses of snow-white fulminate crystals, very regular in shape and of a large size—2 mm. or more in length—are formed. Twinning is very common with these, and a flocculent white precipitate resembling cotton wool, and consisting of long needle-shaped crystals, is frequently deposited. The fulminate crystals so deposited appear to contain water of crystallisation.

Mercury compounds have been generally considered to be inimical to protoplasmic growth, but

I have found fungi growing luxuriously in and under solutions of fulminate of mercury and upon wood, calico, and even the crystals themselves. I am indebted to Miss Lorrain-Smith (of the Natural History Section, British Museum) for kindly identifying the fungi as *Tricoderma viride* and *Acrostalagmus albus* Preuss, respectively, the former growing upon wood and the latter on the calico bag and hence in contact with the crystals.

It is interesting to note in this connection that of the many workers engaged upon the operation of washing and drying fulminate, none of them was ever observed to suffer from the lines on the gums characteristic of mercury poisoning.

These facts accord with the chemical properties of mercury fulminate in that this substance does not give the ordinary reaction for mercury ions.

Estimation.—Various methods have been proposed from time to time for the estimation of mercury fulminate, and for the analysis of cap and detonator compositions. Of these the greater number are concerned with the determination of the mercury content of the salt, and in consequence are similar to the standard schemes for analysis applicable in general to mercury compounds. The following examples are typical:—

1. The fulminate is dissolved in warm, dilute hydrochloric acid, and phosphorous acid is added to reduce the mercuric chloride to mercurous chloride, which is filtered, washed, dried at 105° C., and weighed.

2. The fulminate or composition, which may contain antimony sulphide, is decomposed by warming with dilute hydrochloric acid, with subsequent addition of concentrated hydrochloric acid. If antimony is present a little tartaric acid is added, the solution diluted and filtered to remove silica, etc., made alkaline with ammonia, and ammonium sulphide added. The whole is digested for a time to allow the solution of the precipitated antimony sulphide, filtered through a Gooch crucible, and the precipitate washed, treated with alcohol, followed by carbon bisulphide, then alcohol, dried, and weighed as mercuric sulphide.

Divers and Kawakita (J. Chem. Soc., 1884, 13) proposed to decompose the fulminate with a known amount of concentrated hydrochloric acid, and to titrate with alkali the formic acid generated in the decomposition, allowance being made for the hydrochloric acid.

Jones and Willcox (Chem. News, 1896, 283; this J., 1897, 67) proposed to estimate fulminate, potassium chlorate, and antimony sulphide in detonator compositions by mechanical means. Their method was to extract the fulminate by ammoniacal acetone, then remove the chlorate by solution in water, and finally weigh the insoluble antimony sulphide.

Reecchi (Gaz. Chim. Ital., 1904) showed the method of Jones and Willcox to be inaccurate. He suggests treating the composition with water, heating the solution and decomposing the fulminate with hydrogen sulphide. The sulphides are digested with ammonium sulphide, and mercuric sulphide subsequently precipitated with hydrogen sulphide. In the filtrate the potassium chlorate is converted into chloride and so estimated.

H. W. Brownson (this J., 1905, 382) described a method for the analysis of cap compositions based on the reaction between sodium thiosulphate and fulminate in which alkali is generated. His method was to purify the fulminate by solution in potassium cyanide, and precipitate pure fulminate with dilute nitric acid. 0.04–0.05 grm. of this substance was placed in 50 c.c. of water in a flask and 1 grm. of pure thiosulphate added. When the fulminate is dissolved the solution is diluted to 100 c.c. and 25 c.c. is titrated with acid

in the presence of methyl orange. This serves to standardise the acid in terms of fulminate.

For cap compositions of 15–20% fulminate 0.25 grm. is weighed out in order to keep the weight of the fulminate below 0.05 grm., and hence keep the resulting alkali from reacting with the antimony sulphide. Brownson calls attention to the necessity for titrating at once as secondary reactions set in and lead to low results.

Marshall, in his book on "Explosives," states that the reaction has been studied by Philip and, by G. Peace and himself, and that it is in accordance with the following equation:

The cyanides and cyanates produced can be titrated with acid.

Marshall gives the secondary reaction as follows:

thus accounting for the diminution of the alkalinity when the solution is allowed to stand. He adds that excess of thiosulphate or of potassium iodide restrains the back reaction; for example, ten times as much potassium iodide as fulminate causes only 12% of the alkalinity to disappear in 100 minutes.

Philip (Z. ges. Schiess- u. Sprengstoffw., 1912, 7, 180, 198, 221; this J., 1912, 606) describes a method in which potassium iodide and thiosulphate are added, the alkalinity titrated as usual with N/10 acid, and the residual thiosulphate titrated with iodine.

It will be observed that the equation given by Marshall for the secondary action is arithmetically incorrect, hence it can only be regarded as a statement in symbols. Further it is evident that one molecule of caustic soda remains unaccounted for.

The reaction is in reality more complex than is indicated by Marshall, as various products are obtained according to the conditions. Thus when fulminate is added to a concentrated cold solution of thiosulphate in a proportion greater than 1 mol. to 2 mols. of thiosulphate the resulting solution is faintly opalescent; after about 1½ hours a grey precipitate consisting of fulminate and of mercuric thiocyanate is formed, and the solution smells strongly of ethereal salts and of cyanide. After further standing the smell of cyanide lessens, a mass of fine needle-shaped crystals forms, the precipitate darkens, and mercuric sulphide is formed. The sludge then develops various colours, from green to scarlet, the composition of the mass being indeterminate. The solution still contains thiosulphate, and I consider a portion of the back reaction to be due to the re-formation of this salt. Thus the tetrathionate breaks up into trithionate which then gives rise to mercury sulphate, sulphur dioxide, and sulphur.

One of the sulphur atoms forms thiocyanate with the sodium cyanide, whilst the other helps to regenerate thiosulphate.

The formation of double thiosulphates of sodium and mercury would account for the non-precipitation of mercury salts from dilute solution with subsequent decomposition into mercury sulphide.

In order to test the effect of various concentrations of thiosulphates on the velocity of the back reaction, quantities of 0.3 grm. of mercury fulminate were dissolved in 50 c.c. of thiosulphate solutions of 2%, 10%, 20%, 50%, and 75% concentration respectively, no potassium iodide being used. The fulminate value of the fulminate used was found in the usual manner, i.e., 0.3 grm. was dissolved in 100 c.c. of water containing 3 grms.

of potassium iodide, and 50 c.c. of thiosulphate added. After 5 minutes the solution was titrated with sulphuric acid, using methyl orange as an indicator.

As a mean of three tests 42.2 c.c. was required, and a blank titration required 0.2 c.c., therefore 42 c.c. of acid was equivalent to the fulminate used. 1 c.c. of acid = 0.007115 grm. fulminate.

Time.	Concentration of thiosulphate.				
	2%	10%	20%	50%	75%
	c.c.	c.c.	c.c.	c.c.	c.c.
5 min.	39.2	—	—	—	—
8 "	38.7	41.6	42.0	42.0	42.3
15 "	38.5	40.4	41.7	41.5	41.9
30 "	35.1	40.0	41.0	41.0	41.3
60 "	30.0	39.3	40.2	40.0	40.8

It should be remarked that with 75% concentration it is difficult to get a correct blank owing to the decomposition of the thiosulphate by the acid used in the titration.

From these tests it is evident that the restraining action of thiosulphate is a function of its concentration, but that for practical purposes nothing is gained by using concentrations greater than 20%.

The quantity of fulminate usually taken, *i.e.*, 0.3 grm., does not dissolve readily in the *N*/10 thiosulphate, and if solution is hastened by warming, very erratic results are obtained as the inverse reaction is greatly accelerated. The result of using potassium iodide was of great interest; 0.3 grm. of fulminate when treated with 6 grms. of potassium iodide in 50 c.c. of water required 21.1 c.c. of *N*/10 sulphuric acid to neutralise the resulting alkali, *i.e.*, one half the quantity necessary in the thiosulphate method. With excess of fulminate a white precipitate is formed which yields mercuric iodide on heating or on treatment with acid.

It is desirable to use less expensive reagents than potassium iodide, and I made tests with potassium and sodium chlorides. Six grms. of potassium chloride was added to 50 c.c. of *N*/10 thiosulphate and 0.3 grm. of fulminate was used. In 8 minutes 20 c.c. of acid was required, but it was impossible to get a definite end-point owing to the great rapidity of the secondary reaction. The effect of sodium chloride was similar, but this salt was less energetic in its action.

The experiments described below were performed to see whether acids indifferent to methyl orange could be used, as it seemed possible that by reducing the concentration of the "OH" group, the back reaction might be restrained.

0.3 grm. of fulminate was dissolved in 50 c.c. of *N*/10 thiosulphate, with the addition of 1 grm. of succinic acid; after standing for 8 minutes and titrating 20 c.c. of *N*/10 sulphuric acid was required, and a further quantity after standing 60 minutes took only 9 c.c. of *N*/10 acid. With salicylic acid similar results were obtained. Boric acid was next tested, 3 grms. being added to the usual quantities of fulminate and thiosulphate. In 8 minutes 41.8 c.c. of *N*/10 acid was used and in 60 minutes 39.8 c.c. The effectiveness of boric acid being apparent, a series of titrations was made and their general agreement proved that boric acid had a marked restraining action, and that it could efficiently replace potassium iodide.

Sodium dihydrogen phosphate is neutral to methyl orange, but acid to litmus, and experiments were therefore made with this salt in order to test the view I had formed, *i.e.*, that it is the presence of free sodium hydroxide which determines the back reaction. As before, 0.3 grm. of

fulminate and 50 c.c. of thiosulphate were used in each experiment.

Weight of phosphate.	Times of standing.			
	8 min.	15 min.	30 min.	60 min.
gm.	c.c.	c.c.	c.c.	c.c.
0.17	38.7	37.4	34.3	32.7
0.5	42.0	42.1	41.6	41.2
1.0	41.95	42.1	42.1	42.0

The end point is not very distinct with the greater concentration, but the results tend to confirm the view I have put forward.

I have often found the need for a complete method of estimating the constituents of detonators when only one sample was available. It is possible to remove the composition from the shell by deforming the latter in two directions at right angles to one another, and to estimate the fulminate by means of thiosulphate, the antimony sulphide as insoluble matter, and the chlorate by difference. But methods by difference are not usually satisfactory, save when dealing with a fairly standard product. Further, it is frequently necessary to determine whether age or exposure has caused a deterioration in the fulminate; for example, it may have reacted with the other constituents, or with the metal envelope. In such cases it is advisable to determine the total mercury in order to find the weight of fulminate originally used, and also the fulminate value to serve as a measure of its decomposition, and finally estimate all other constituents such as antimony sulphide, potassium chlorate, organic substances, etc.

It seemed to me that the first step to be taken was to find the fulminate value by the thiosulphate method and then to remove mercury quantitatively, leaving the solution in a suitable state for an estimation of chlorate.

Volhard's method of separating the mercury, *i.e.*, by precipitation with fresh ammonium sulphide, treatment with caustic soda and destruction of the sulpho salt with ammonium nitrate, was unsatisfactory and other methods were sought for.

I then tried removing the mercury from the thionate-thiosulphate mixture by means of hydrazine sulphate or the corresponding hydroxylamine salt. With hydrazine sulphate a very clean separation was possible, for example:—0.32 grm. of pure fulminate and 0.1082 grm. of potassium chlorate were dissolved in hot water, 20 c.c. of *N*/10 sodium hydroxide solution was added, followed by 1 grm. of hydrazine sulphate; on heating a black precipitate was formed, leaving a clear solution which filtered readily. The precipitate was washed, dissolved in concentrated nitric acid, heated to oxidise the mercury completely, cooled, diluted, and titrated with thiocyanate in presence of ferric sulphate indicator. 0.224 grm. of mercury was found (theory, 0.226 grm.).

The chlorate in the filtrate was at the same time reduced; the weight found by Volhard's method was 0.1072 grm., some loss having been occasioned by the oxidation of the solution by means of nitric acid.

No difficulty was experienced in the hydrazine method and concordant results were obtained, but as a further supply of this material could not be obtained the method had to be superseded.

The next reagent used was soda-glucose.

(A) Reduction of chlorate alone. 0.3 grm. of potassium chlorate was dissolved in 50 c.c. of water, 100 c.c. of a mixture of 10% glucose and 10% caustic soda was added, and after boiling for 30 minutes the mixture was cooled, the remaining glucose oxidised with 25 c.c. of nitric acid, and the

chloride precipitated by means of silver nitrate. In three experiments in which 0.3 gm. of chlorate was used the amounts found were 0.205, 0.296, and 0.293 gm. respectively.

(b) Reduction of chlorate in presence of sodium thiosulphate. 50 c.c. of thiosulphate was added to 0.3 gm. of chlorate and 100 c.c. of soda-glucose and treated as before. It was noticed that some sulphur was precipitated on addition of the nitric acid. In three experiments the amounts of chlorate found were 0.298, 0.298, and 0.297 gm.

(c) Reduction of chlorate in presence of mercury fulminate. 0.3 gm. of potassium chlorate and 0.3 gm. of fulminate were treated as above; after reduction the precipitate of mercury and mercury sulphide was filtered off, but some difficulty was experienced in completely freeing the filtrate from mercury compounds.

The results obtained in successive experiments were 0.294, 0.296, 0.298, 0.32, 0.31, and 0.301 gm. (the last two precipitates were found to contain mercury). Unfortunately the mercury could not be accurately estimated owing to the precipitate running through the filtering medium, and all the results were low and not sufficiently accurate to justify the method.

Ferrous sulphate was next tried as the reducing agent, the following method being used:—0.3 gm. of fulminate and 0.3 gm. of chlorate are dissolved in 50 c.c. of thiosulphate, and 3 grms. of boric acid added, and the whole well shaken for three minutes. The fulminate value is then determined by titrating with *N/10* sulphuric acid which has been standardised against pure fulminate in presence of boric acid, the indicator used being methyl orange. If antimony sulphide is present it is filtered off on a Gooch crucible, washed, dried, and weighed. To the solution 100 c.c. of 10% ferrous sulphate, containing 1 c.c. of free sulphuric acid, is added, and it is boiled for 30 minutes. After standing for a short time, it is filtered through a small paper, and the precipitate well washed with water. An excess of nitric acid is added to the filtrate to oxidise the ferrous sulphate, 50 c.c. of *N/10* silver nitrate is added, and the excess titrated with *N/10* ammonium thiocyanate. The reduced mercury precipitate, which contains some sulphide, is dissolved off the paper with *aqua regia* and the solution diluted, neutralised with ammonia, and made slightly acid with hydrochloric acid. The sulphide is now precipitated with hydrogen sulphide, filtered in a Gooch crucible, washed with hot water, followed by alcohol, carbon bisulphide, and alcohol again, dried at 105° C., and weighed as mercury sulphide. The free sulphuric acid in the ferrous sulphate quantitatively precipitates mercury sulphide from the mercury thionate solution.

The method I now use for the complete analysis of detonator composition serves to determine fulminate value, total mercury, antimony sulphide and insoluble matter, and potassium chlorate.

The detonator to be examined, if of the closed-over type, has its lugs cut by means of dental forceps; if of the "obturator" type careful squeezing by means of a shielded press, followed by manipulation with forceps, serves to open it. The composition is then cracked by deforming the shell across two diameters at right angles, when the bulk of it is readily removed. The portions remaining adhering to the walls are loosened by the use of a splinter of wood, using alcohol if necessary. By weighing the detonator before and the cleaned shell afterwards the weight of charge is found. The dried and weighed composition is then broken by moistening with alcohol and gently triturating with a glass rod.

The quantity of thiosulphate to be used is dependent on the weight of the composition. For quantities up to 0.3 gm. 50 c.c. of approximately

N/10 thiosulphate is used; for larger weights such as 1.5 grms. 50 c.c. of *N/1* thiosulphate should be taken. 0.3 gm. of boric acid is added and the whole well shaken, using a glass rod to aid solution. After 3 minutes a few drops of methyl orange are added and sulphuric acid added till neutral. Any antimony sulphide is filtered off, washed, and weighed, but if powdered glass is present the antimony is estimated volumetrically.

The solution containing the mercury compounds, etc., is next treated with 100 c.c. of 10% ferrous sulphate solution containing 1 c.c. of free sulphuric acid. It is boiled for 30 minutes, the precipitated mercuric sulphide is filtered off, washed, dissolved in *aqua regia*, the solution diluted, neutralised with ammonia, acidified with hydrochloric acid, and precipitated with hydrogen sulphide.

The precipitate is washed, the final washing being done with alcohol, carbon bisulphide, and alcohol again, dried, and weighed. The filtrate containing the reduced chlorate is oxidised with nitric acid, excess of silver nitrate added, and titrated with ammonium thiocyanate. An alternative method for the mercury sulphide precipitate is to dissolve in *aqua regia* containing sulphuric acid, evaporate until fumes are evolved, to remove hydrochloric acid, dilute, and estimate volumetrically with thiocyanate.

I wish to thank Messrs. White and Poppe for their permission to communicate these results, and Miss G. M. Leeson for her helpful observations.

DISCUSSION.

Dr. D. F. TWISS, referring to the estimation of mercury fulminate, enquired whether the author had tested the practicability of the alkalimetric titration of a mixture of sodium cyanide and cyanate with standard mineral acid and methyl orange; he was of the opinion that on account of the hydrolysis of cyanic acid into ammonia and carbon dioxide, sodium cyanate would neutralise more than an equimolecular proportion of a monobasic acid such as hydrochloric acid and that the mixture of sodium cyanide and cyanate would therefore not possess a neutralising power equivalent to its content of sodium. With reference to the constitutional formula attributed in the paper to mercury fulminate, he suggested that fulminic acid was now more generally accepted as being an isomeride and not a polymeride of cyanic acid; according to this view there was no direct linkage between the carbon atoms in the acid radicals of mercury fulminate and these atoms were regarded as examples of bivalent carbon, their only attachment being to the nitrogen atom by means of a double bond.

Dr. E. B. MAXTED asked for information as to the reaction between mercury fulminate and potassium iodide. What happened to the CNO? Were stability tests against heat made? In the case of mercuric nitride this was easily done in a capillary tube in a glycerin bath, and it occurred to him whether a similar method could be adopted in relation to mercuric fulminate.

Dr. H. W. BROWNSDON asked for information regarding the preparation of the detonator sections. He doubted the author's conclusion as to the breaking down of the crystalline fulminate into an amorphous variety under heavy pressure and preferred to consider the differences observed as due to crystal size only. When he had first noticed the formation of alkali on treating fulminate with thiosulphate and examined the possibilities of using this reaction as a basis for the quantitative estimation of fulminate, the interference of secondary reactions had been the chief disturbing factor which had to be overcome in order to obtain reliable results.

Mr. F. C. A. H. LANTSBERRY expressed the view, with regard to the breaking up of crystals, that pressure was not likely to cause crystalline material to become amorphous, because generally the crystals occupied a larger space.

Mr. F. H. ALCOCK did not think there was any objection to dealing with the mercury content by precipitation with hypophosphites; it was a reliable method in most cases.

Dr. TROTTER enquired if the colour of fulminate had any bearing on the question of efficiency. There was an idea that the lighter the colour the greater the efficiency.

Mr. HEAVEN, in reply, regretted that he could not answer Dr. Twiss's question. He could not explain the course of the reaction between mercury fulminate and potassium iodide. If a small quantity of the former were used the iodide dissolved it with great readiness. It indicated the presence of a double compound. With an excess of fulminate, however, a point was reached when a fine white precipitate containing iodine was obtained. As to what the actual reaction was he did not know, but alkalinity was developed. The heat test was not followed as a matter of routine or use. He had failed to get a sharp melting point. There was evidence of mercuric vapours being given off at temperatures approaching 150°C . He had used the term "amorphous" rather loosely; there was no evidence of the crystalline form up to magnification of 400 diameters. Dr. Brownson's analytical scheme had been of great service to him. Bar tests had been employed on detonators on the Hopkinson principle. The question of whether a relationship existed between colour and efficiency remained unsettled. The balance of opinion was that there was no relationship.

Nottingham Section.

Meeting held at Nottingham on Wednesday, April 24th, 1918.

DR. E. M. CAVEN IN THE CHAIR.

A MODIFIED MERCURIAL VISCOMETER FOR DETERMINING THE VISCOSITY OF VOLATILE LIQUIDS.

BY F. M. LIDSTONE.

In a paper read in January, 1917 (this Journal, 1917, 270), a description was given of a mercurial viscometer and its application to the measurement of the viscosity of lubricating oils. Since that paper was written, however, liquids other than oils have been at different times run through the instrument, with the result that it has been found that the apparatus as there described is not adapted to the testing of liquids of high vapour tension, inasmuch as a cushion of vapour forms at the junction of the mercury and liquid being tested.

On consideration it will be seen that this takes place when the vapour tension is greater than $P-H$, where P is the atmospheric pressure and H the head of mercury in the viscometer.

The apparatus to be described here was designed to remedy this defect in the readiest and simplest manner by means of an attachment which would not interfere with the ordinary working of the viscometer and would also allow the usual constants of the instrument to be used without any alteration.

A is a mercury manometer which registers the increase of pressure, which is applied equally to

the top and bottom of the moving column in the viscometer. If this pressure be p , the atmospheric pressure P , and the head of mercury in the viscometer H , then if $P+p-H$ be equal to or exceed the vapour tension of the liquid, at the temperature of the experiment, there will be no separation of the mercury and liquid taking place during the running.

The pressure is conveniently applied by means of a hand bellows, B, and the stopcock, C, is then closed. If the rubber connections are properly airtight there will be no need to pump in any more air during the running; also it will be seen that no matter how great is the pressure, p , the ordinary constants of the instrument remain unchanged.

Examples of liquids which cannot be run at ordinary temperatures through this viscometer without the application of increased pressure are:—Ether-alcohol solutions of nitrocellulose, acetone solutions of cellulose acetate, solutions of rubber in volatile solvents, etc. It can be used for all volatile liquids at high temperatures; for example, with this apparatus the viscosity of ether may be determined at temperatures much above its normal boiling-point.

There are other useful purposes which this attachment can be made to serve. Thus thin and quick-running liquids can be made to take a longer time by applying a known pressure at the end L, whilst the end D remains open; if the decrease in the head is accurately measured by the manometer the readings can easily be converted. Conversely, a known pressure can be applied at D, L remaining open, and a thick and slow-running oil may thus be made to run more rapidly. When pressures are applied in this manner, care must be taken to tap the manometer frequently in order to overcome the peculiar lag in the mercury and to get a correct measure of the pressure which is being applied. A globe or flask of large capacity must also be interposed in order that the small change in pressure due to the volume of the mercury which is leaving the viscometer may not have any

sensible effect. Of course, when the pressure is applied simultaneously to top and bottom, as in the case of volatile liquids, these precautions are not necessary. After a thick oil has been run, and the reading taken, it also saves time to force the oil through the viscometer by applying pressure at the top of the column instead of waiting for the oil to drain out. The tube is then washed with ether as usual.

The author takes this opportunity of correcting a mistake which appeared in the previous paper (*loc. cit.*). The error referred to was in the formula there given to correct for the time taken by the mercury in the case of very mobile liquids. As will be seen, it is impossible to give a simple formula which is mathematically correct for all cases, but a very close approximation is arrived at as follows:—

Let t = time taken by mercury flowing freely, v = mean velocity of mercury flowing freely, T = time taken by mercury retarded by oil, V = mean velocity of mercury retarded by oil, and m = mass of mercury.

Then $\frac{1}{2}m(v^2 - V^2)$ = work spent on oil. Hence when V is made infinitesimally small, $\frac{1}{2}mv^2$ represents the total available work which the mercury can do. The time, T , can then be converted into the time which would be taken if the whole of the available work were spent on the oil, this time being:—

$$T \frac{\frac{1}{2}m(v^2 - V^2)}{\frac{1}{2}mv^2} = T \left(\frac{1}{t^2} - \frac{1}{T^2} \right) = T \cdot \frac{t^2}{T^2}$$

This time would then be proportional to the absolute viscosity if the mass and kinetic energy of the liquid could be neglected, or, on the other hand, if t could be taken to represent the time which the mercury would take together with an imaginary liquid of unit density, but with absolutely no viscosity, the equation could be written:—

$$\eta = k \left\{ T - \frac{\left(t \frac{H+h}{H+hd} \right)^2}{T} \right\} \frac{H+hd}{H+h}$$

where H is the mean head of mercury, h the mean head of liquid of unit density, and d the density of the oil.

Now by making the bore of the tube below the bulb relatively large, the time, t , becomes small and its correction negligible. The equation then becomes:—

$$\eta = k \left(T - \frac{t^2}{T} \right) \frac{H+hd}{H+h}$$

or by putting $\frac{H}{h}$ equal to n and $\frac{k}{1+n}$ equal to K the equation can be written:—

$$\eta = K \left(T - \frac{t^2}{T} \right) (d + n)$$

where K and n are constants, T is the observed time of running, t is time taken by mercury alone, and d is specific gravity of the oil.

In calibrating the viscometer the density, d , is taken as unity for water at 60° F., as in actual practice specific gravities of liquids are usually referred to water at this temperature, and thus a number of small corrections are obviated.

My thanks are due to Mr. L. Archbutt for permission to make the necessary experiments and the apparatus itself in the Chemical Laboratory of the Midland Railway Company at Derby, and also to Mr. R. W. Lunn for kindly preparing the sketch.

DISCUSSION.

Mr. J. M. WILKIE said that when using the ordinary Redwood viscometer it was necessary

to employ considerable quantities of oil, and the operation required the expenditure of considerable time. As a result of Mr. Liddstone's work an apparatus has been devised which gave results comparable with those obtained by the Redwood apparatus and furthermore made it possible to obtain results in a much shorter time and with the use of considerably less material. The apparatus had been adopted in Messrs. Boots' Analytical Laboratory, and the results had been entirely satisfactory.

Mr. Woodhouse said that at present he was using the Coleman-Archbutt glass apparatus and had found that it gave reliable results. He had made one slight modification of this apparatus by surrounding the efflux tube with a glass bulb which was immersed in water, so as to maintain the oil inside the tube at the same temperature as the oil outside the efflux tube prior to leaving it. By this means he had obtained results which compared favourably with figures obtained with the Redwood apparatus.

THE INFLUENCE OF SMALL QUANTITIES OF SOME METALLIC ELEMENTS ON THE MECHANICAL PROPERTIES OF BRASS.

BY E. MILLINGTON.

The experiments to be described in this note were carried out to ascertain the effect of some metallic elements on the mechanical properties of a certain type of brass.

Shepherd, Carpenter, Edwards, Hudson, Hoyt, and others have made exhaustive investigations into the constitution of brasses, and as a result various diagrams have been framed embodying their conclusions. It is by the aid of these diagrams that the mechanical properties can to some extent at least be predicted.

For certain purposes the strength of ordinary brass is insufficient and it becomes necessary to modify the alloy in accordance with the conditions to be met. It is well known that the addition of other elements may profoundly modify the physical properties of the pure brass, either by exerting their own peculiar properties or by introducing an additional phase, or phases. It is, therefore, necessary so to adjust the mixture by selecting the element or elements to be added which are the most suitable for the purpose in view.

In the case of copper-zinc-tin alloys the theoretical and practical side has been worked out by Hudson, Hoyt, Thurston, and others, and from their results it is possible to predict what effect is likely to be produced in given circumstances. But as many other elements are employed and as the information concerning them was not available, it was decided to investigate the matter as far as the immediate requirements were concerned.

In the alloys to be described the choice of metals, other than copper and zinc, was limited to tin, iron, manganese, and aluminium. Owing to the restrictions in the use of pure metal for industrial purposes it was only possible to use materials of commercial purity.

Since the object of these tests was to represent castings as such, without any subsequent treatment, the specimens to be tested were cast both in sand and iron chill moulds, and since the work had to represent ordinary foundry conditions nothing further than foundry practice was observed in the preparation of the alloys, but at the same time every care was taken with the melting and the casting of the metal.

The actual figures as obtained from tests are given in the tables and also plotted in Fig. 3. The effect of different rates of cooling, as produced when the metal is cast in sand or in iron chill moulds, is clearly shown in this figure.

The range covered by the alloys was Cu 56—60%, Zn 37—41%, the difference being made up by the addition of a third element. It will, therefore, be seen that the brass was of that type known as Muntz metal.

From the constitutional diagram of the copper-zinc series, a portion of which is shown in Fig. 1, it will be seen that for varying composition corresponding phases are met with in normally cooled or annealed solid alloys. Thus in alloys containing not less than 63% of copper, the system is one of single phase, viz., α ; with less than 63% and more than 53% of copper, the system is duplex α and β . In the interval of

selves in any given alloy. The α constituent for example is the one having the greatest ductility, while β is the one imparting the greatest strength. The presence of either γ or δ in a brass may seriously affect the ductility and also the strength of the alloy.

As an example illustrating the effect of the γ -phase the following figures, which have been kindly furnished me by Mr. Archbutt, may be quoted:—

Analysis of the alloys.

	No. 1. %	No. 2. %
Copper	60.70	50.69
Tin	0.01	0.02
Lead	2.06	1.22
Aluminium	0.06	0.49
Iron	0.04	0.03
Nickel	0.07	0.03
Zinc	37.02	47.46
	99.06	99.94
Yield point, tons per square inch	9.2	8.4
Maximum stress, tons per square inch	24.4	16.7
Elongation % on 2-inch	41.0	4.0

The explanation for the remarkable difference in physical properties of the two alloys is to be found in their micro-structure, the good properties being associated with the duplex $\alpha + \beta$, while the inferior strength accompanies the β and γ formation.

Thus, the subject resolves itself into one having for its object the reinforcing of the α and β duplex by means of the addition of other elements in suitable proportions which shall give the necessary strength, at the same time avoiding the formation of the two deleterious phases γ and δ .

Owing to the similarity in appearance of the two constituents γ and δ when viewed through the microscope it is difficult to distinguish with certainty one from the other in a ternary alloy, since they both present a bluish colour after etching and for this reason they will be referred to as a blue constituent.

The results embodied in the diagram, Fig. 3, will now be considered, commencing with the copper-zinc alloy which forms the basis of this series. The composition of this alloy is Cu 59.72 and Zn 40.18%. The mechanical properties in the sand-cast specimen are yield-point 8.4, and maximum stress 22.7 tons per square inch, with an elongation on 2 ins. of 47.7%. These figures are notably increased in the chill-casting as will be seen from the diagram.

FIG. 2.

Copper, zinc, tin, ternary diagram.

Since a similar relationship holds good in sand- and chill-cast specimens it will only be necessary here to consider the results in one case. Selecting the sand casting for this purpose, it will be seen that the introduction of 1.11% of tin, which in this case displaces the copper, produces an increase in yield point of 19 and maximum stress of 11% respectively, at the same time lowering the elongation by 61%. This reduction in elongation does not appear to be due to the presence of a third constituent, as microscopical examination failed to reveal any and this is in accord with the diagram (Fig. 2), which shows at 58.23% of copper only

FIG. 1.

Equilibrium diagram of copper-zinc alloys.

61%—53% copper, again, the system is one of single phase viz., β^* , while 51%—40% copper produces the duplex γ and β .

The ternary system of copper-zinc-tin has received some attention by Hudson and Jones. Their diagram (Fig. 2) represents this system with some degree of accuracy, covering alloys from 50%—70% copper and 0—5% tin.

It will be noticed that the three branches α , α and β , and β and γ of the copper-zinc system are represented. The chief features to observe are the varying solubility of tin and the phase-producing effect in the branches referred to. Commencing at 70% copper it will be seen that the solubility of tin below the line D—C decreases with the decrease of copper down to 63%. Below this line the α phase is retained while above it the duplex $\alpha + \delta$ makes its appearance. On the other hand in the branch lying below the line K—G the solubility of tin increases with a still further increase of copper.

Above this line the three-phase system $\alpha-\beta-\delta$ is found.

In the area G.E.F. the solubility of tin again falls, giving rise to the single-phase alloy β ; while above the line C—F the duplex $\beta + \gamma$ occurs.

In using the constitutional diagram it is important to remember the respective properties of the possible phases which may present them-

*Carpenter and Edwards regard this constituent as a duplex $\alpha + \gamma$ (see J. Inst. Metals, 1911, 5). For practical purposes the author uses Shepherd's diagrams (J. Inst. Metals, 1901, 1).

the normal duplex $\alpha + \beta$ possible. The only conclusion is that other causes are present and this is probably due to the hardening influence of the tin itself. Further increase of tin to 2.13% raises the yield point by 33%, and the maximum stress by 4%, and reduces the elongation by 83%, compared with the copper zinc basis alloy. In this case the blue etching constituent was found to be present, which is supported by Fig. 2, showing that with copper at 57.51% (the copper content of the alloy) the three phases α , β , and δ , would be present.

Fig. 3.
Ternary brass alloys.

Displacing tin with 1.16% manganese increases the yield and maximum stress by 11.9% and 12.3% respectively, with a decrease in elongation of 25.5% compared with the original brass. An increase in manganese to 2.07% results in the same tenacity being retained but gives a much improved elongation, being actually 2.7% greater. In this instance in the chill cast specimen elongation is less by 6% than in the corresponding basis alloy. A still further increase of manganese to 2.8% has a very marked effect by considerably raising the strength, the yield and maximum stress increasing by 42.7% and 18.9%, respectively; at the same time the elongation is reduced by

lites in large β crystals, giving every evidence of brittle material.

The presence of 1.92% of aluminium notably raises the yield and maximum strength, viz., by 88.9% and 23.3% respectively, and simultaneously reduces the elongation by 88.4%. Microscopical examination revealed the presence of the blue etching constituent in a structure which is otherwise apparently a single phase β . This occurs in the presence of 59.06% of copper, which makes the case more remarkable as in the ordinary brass such a condition would normally not be found with more than 54% of copper. It is not, therefore, surprising that the ductility should fall.

The effect of 1.2% of iron is to increase the yield point 9.5% and the maximum strength 12.7%; at the same time the elongation, while being much superior to that of the aluminium alloys, is reduced by 37.1%. The presence of 1.88% of iron notably raises the yield point but slightly reduces the maximum stress compared with 1.2% alloy; at the same time the elongation is seriously impaired. While microscopical examination failed to reveal any blue etching constituent the 1.88% alloy contained this phase and this probably accounts for the loss in ductility.

It will, therefore, be seen that the addition of the third element to the binary copper-zinc alloy has been limited to 2.0%, with the exception of manganese, which was carried to 2.81%, and as this served the immediate purpose the investigation was concluded.

The author is fully aware of the limited scope covered by the paper. What is now required is to extend the investigation into the still more complex systems and this as time and opportunity permits is being carried out. However the results of this extension up to the present do not admit of conclusions being drawn and much requires to be done before it can be completed.

Before concluding reference may be made to an experiment which has some bearing on the subject of greater complexity. An alloy having the composition, Cu 54.10, Pb 0.42, Al 0.40, Fe 2.51, Mn 0.89, Ni 3.58, Zn 38.03%, gave in the testing machine:—

State.	Tons per square inch.		Elongation, % on 2 in.	Contraction of area, %.
	Yield.	Max. stress.		
Cast in sand.....	11.6	23.7	13.5	23.1
Cast in iron chill mould.....	13.2	32.5	43.0	42.0

62.2%. A microscopical examination failed to show anything but the duplex $\alpha + \beta$ structure. The remarkable reduction of elongation in the case of 2.8% manganese can only be accounted for by the hardening effect of this element itself and this is confirmed by the corresponding increase in strength.

The addition of 1.06% of aluminium results in a very marked effect on the ductility of the alloy, reducing this property by 72.7% in the sand and 85.2% in chill casting respectively, at the

These figures present two striking features, the first being the great difference between the sand cast and the chill cast specimens and the second the superior results obtained by the latter method of casting.

With the object of increasing the strength of this alloy tin was added and the following is the analysis of the resulting alloy:—Cu 53.86, Sn 0.88, Pb 0.43, Al 0.38, Fe 2.31, Mn 0.84, Ni 3.33, Zn 38.05%; on testing the following results were obtained:—

State.	Tons per square inch.		Elongation, % on 2 in.	Contraction of area, %.
	Yield.	Max. stress.		
Cast in sand.....	18.0	26.4	5.5	15.2
	16.8	29.5	7.5	15.2
Cast in iron chill mould.....	18.8	33.8	13.0	21.6
	19.2	35.7	15.0	21.6

same time increasing the strength. It will be noticed that 1.0% of aluminium has an effect similar to that produced by 2.13% of tin. The structure of this alloy was coarse, acicular crystal-

These figures require no comment; the strength is very much improved, particularly the yield point, but at the expense of a serious loss of ductility.

Time has not permitted a microscopical examination being made on these alloys, in which case the explanation for the difference in the ductility would most likely be found, especially having regard to the effect of tin and iron previously discussed.

In conclusion I desire to thank my friends at the Midland Railway Company for their kind assistance, particularly Messrs. Archbutt and Adams, the former for the analyses of the alloys and the latter for the photomicrography.

DISCUSSION.

The CHAIRMAN asked if the metals indicated in Fig. 3. were added so that only one was present at a time in addition to the zinc and copper.

Dr. E. P. HEDLEY remarked that the equilibrium diagram (Fig. 1) differed from that originally published by Shepherd, a horizontal line having been inserted from the point representing 37% to 60% Zn at a temperature slightly below 500° C. He asked the reason for this alteration. From the appearance of the first photomicrograph it might be imagined that there was more than one phase present, whereas the photograph was intended to represent the homogeneous α -phase. The paper emphasised the importance of considering the effect of mere traces of metal. He referred to the amount of work that would be required to obtain equilibrium diagrams for the complex alloys referred to in the latter part of the paper, containing seven and eight metals respectively. The difficulty of making a complete metallographic study of a system of alloys increased very rapidly with the number of component metals and a quaternary system would necessitate several thousand determinations being made.

Mr. MARSHALL asked for some information as to the best method of treating swarf.

Mr. WYER asked if any special temper was given to the samples used in the experiments referred to. He also mentioned that his firm had made an attempt to increase the temper of an ingot metal by the addition of ferromanganese but that the result had been a failure.

Mr. MILLINGTON, in replying to Dr. Cayen, said that Fig. 3 was intended to show the effect of adding one metal at a time to the mixture of copper and zinc. The line referred to by Dr. Hedley in the equilibrium diagram had been omitted

by Shepherd in his diagram. There was, however, no doubt that such a line existed and should be embodied in the diagram as it represented a series of heat evolutions originally observed by Roberts Austen (4th Report to the Alloys Research Committee, Inst. Mech. Eng., 1897, p. 36, plates 2 and 3), and the line had recently been determined by Carpenter and Edwards (J. Inst. Metals, 1911). There was some doubt as to the real significance to be attached to this line. Carpenter and Edwards considered that at this

temperature (470° C.) the β -phase underwent decomposition into $\alpha + \gamma$, whereas Hudson (J. Inst. Metals, 1914, 88-99) considered it to be due to a polymorphic transformation of the β constituent and to represent the areas below the line as composed of $\alpha + \beta$, β , $\beta + \gamma$ respectively. For practical purposes it was sufficient to recognise the existence of this line and to work on Shepherd and Hudson's conclusions regarding the phases present. For these reasons in Fig. 1. Carpenter and Edwards' results were shown in full lines while Shepherd's conclusions were given in dotted line. The reason for the heterogeneous appearance of the α phase in the first photomicrograph was owing to the fact that during the solidification of the alloy the final condition was not at once arrived at, as the central part of each individual crystal of such a solid solution when first formed contained considerably less of the solute than the liquid alloy from which it was deposited, and as solidification proceeded the "core" of relatively dilute solution was surrounded by successive layers of more concentrated solution. The result was the appearance of these "cores" within the polyhedral crystals. If such an alloy were annealed the "cores" disappeared and the alloy then appeared perfectly homogeneous. However, if the annealing had been accompanied by mechanical work the disappearance of the "cores" was accompanied by the formation of numberless "twinned" crystals. In the preparation of equilibrium diagrams it was essential that the component metals should be as pure as possible if the diagrams were to be of any practical value. The addition of a third component might result in the precipitation of one of the other components which had been previously in solution, whereas the addition of another might result in the whole becoming a homogeneous mass.

In connection with the melting of swarf (the turnings obtained from the working of brass) he stated that the operation could be accomplished by employing any of the standard forms of heating apparatus. It was advisable to melt a small quantity of the swarf at the commencement and gradually to add the remainder to the liquid, in small quantities at a time, until all was molten. By the addition of an amount of aluminium equal to 0.25% of the weight of metal treated, the resulting alloy was much superior owing to the deoxidising effect of this metal.

In the preparation of the complex alloys referred to, the chief point to be borne in mind was first to melt the metal or preparatory alloy which possessed the highest melting point and then to add the other constituents in the order of their melting points. By this means overheating of the mass was obviated and oxidation reduced to a minimum. For good melting the molten metal should be kept covered with charcoal and a suitable flux; one that had given good results was composed of two parts of common salt and one part of borax.

MR. W. MED. MACKEY IN THE CHAIR.

PRELIMINARY NOTE ON THE PRESENCE OF BISMUTH IN THE HUMAN BRAIN.

BY T. FAIRLEY, F.I.C., AND B. A. BURRELL, F.I.C.

Some time ago we received the viscera of a man whose death was suspected to be due to slow poisoning. The subject, who was in middle life, had been ill for some months and during the illness had taken considerable quantities of preparations of bismuth, which had been prescribed by his medical attendant. During the course of the analysis we were therefore not surprised to find this element present in the intestines, stomach, liver, spleen, kidneys, and bladder, as Hale White says it is very slowly absorbed and excreted chiefly in the urine, and may be found in the liver, kidneys, spleen, and nervous system.

Amongst the organs examined was a portion of the brain; this also showed distinct evidence of the presence of bismuth, and we hope at some future date to give the quantity present in this and other organs.

We have not been able to find any recorded instance of bismuth being detected in the human brain, and it is an interesting speculation as to what action this metal will have on the brain substance and therefore on the mental condition of those who are taking a long course of this widely-used drug.

The extensive use of bismuth preparations is shown by the following, quoted from Martindale and Westcott's "Extra Pharmacopoeia," 8th Ed., 1895:—"Analysis of the ingredients of 25,500 prescriptions showed Tinct. Nucis Vom. to occupy the highest place, having entered into 2168 prescriptions, and bismuth preparations, including the nitrate, carbonate, and Liq. Bism. et Am. Cit., to be ninth on the list, having entered into 1112 prescriptions.

The method used for the extraction of bismuth was that usually given in works on toxicology. A very delicate test for bismuth (which will detect 0.00025 grm. of Bi in copper) is that of Abel and Field.

DISCUSSION.

Mr. JAMES MILLER asked whether the lead iodide test was regarded as more delicate than potassium iodide.

Mr. BURRELL replied that it was advised by Abel and Field for the detection of bismuth in copper, and that he certainly thought it the most delicate, after comparing it with other tests.

FILTERING MEDIUM USED IN THE ESTIMATION OF WOODY FIBRE.

BY T. FAIRLEY, F.I.C., AND B. A. BURRELL, F.I.C.

In a recent note (Analyst, 1918, 43, 31), J. A. and E. W. Voelcker emphasise the desirability of some agreement being made as to the strength of the acid and alkali used in the determination of woody, or, as it is sometimes called, crude fibre in cattle feeding stuffs. In common with what we believe to be a large majority of chemists, we use the 1.25% strength of acid and alkali, as against the 2% strength recommended by Messrs. Voelcker.

We think that the filtering medium used in this empirical method is of almost equal importance as the strength of the acid and alkali. The majority of chemists use a piece of fine linen (Frankland's "Agricultural Analysis" says fine muslin) as recommended by most of the text books on agricultural analysis. Wiley states that the first filtration (acid) may be made through linen, glass wool, or asbestos, and the second (alkali) through a Gooch crucible. We submit that "fine linen" is an expression capable of a wide and variable meaning, and it follows that the mesh will also be variable; for instance comparable results could not be obtained by using in one instance a fine linen pocket handkerchief and in another a fine linen tablecloth as the filtering medium, though both of these are equally "fine linen."

In the dry state, the mesh of a fine linen handkerchief in several we have examined ranged from about 90 to 110 to the linear inch. We have not made any determinations when wet as it would be if used as a filter, though obviously it will be altered by the swelling of the fibre, and there is also the action of the dilute acid and alkali to be considered.

Owing to the uncertain character of "fine linen" we have discarded its use as a filtering medium and use instead copper gauze with 100 meshes* to the linear inch.

The results obtained with such gauze are somewhat lower than when linen is used, as the following figures show:—

	Linseed cake.	Barley meal.	Palm kernel meal.	Bran.
	%	%	%	%
Gauze	8.3	6.1	18.4	10.6
Lin.	9.5	6.9	20.0	12.2

DISCUSSION.

The CHAIRMAN asked if the gauze itself was unaffected.

Mr. BURRELL replied that it was. It could be used for months if carefully washed and dried.

Mr. F. W. RICHARDSON did not think it would be possible to have a process that would be applicable to all substances, because the fibres varied greatly in different materials. He had tried various processes, but now he always used an electrical centrifuge, working at a very high rate of revolution. This saved the whole process of filtration, and, of course, avoided the problem of the size of the mesh. In the case of flours he emulsified them and then treated them with malt extract at 155° F., afterwards adding the equivalent of 0.2% of hydrochloric acid and using a very pure solution of pepsin. He thus got a very complete digestion without the action of acids or alkalis, and obtained a good idea of the amount of indigestible cellulose. He thought the copper gauze would not eliminate the whole of this, since it was possible that it would

* The same size as is used for testing the "fineness" of basic slags.

not prevent the more finely divided particles from passing through.

Dr. H. INGLE said it was well known (Ingle, this J., 1904, 1197) that corky matter could only be saponified in a rather strong solution, and he thought the 1½ or 2% mentioned by the authors would not do for such matter. The so-called indigestible matter might contain cork, and he asked if there was any chance of its remaining unsaponified. Personally he thought it would.

Major MARPLES said it seemed to him that there was very little to choose between the two methods. In using a centrifuge he had found difficulty in the washing, and this he thought was quite as objectionable as the trouble of filtration.

Mr. BURRELL, replying, pointed out that the method suggested was purely an empirical one, and was capable of improvement, but still it served a useful purpose. The point suggested by Dr. Ingle was a very interesting one, because—with reference to the Voelckers' note—the usual strength of solution used in this country, on the Continent, and in America was 1½% acid, followed by 1½% alkali. In their laboratory they had used 1½% solutions for thirty years, but the Voelckers affirmed that this was not sufficient to effect hydrolysis and that 2% was necessary.

Communications.

THE COMPARATIVE EFFECT OF ORGANIC AND INORGANIC ACCELERATORS IN VULCANISING RUBBER.

BY HENRY P. STEVENS.

Various statements have been made regarding the comparative accelerating effect of inorganic accelerators, such as litharge and magnesia, and the more modern organic accelerators.¹ It has been stated that relatively large quantities of the former are necessary to produce an accelerating effect comparable with that obtained by means of small quantities of the latter. It is also stated that the physical properties of the rubber vulcanised with inorganic accelerators differ from those obtained with organic accelerators, and it appears to be generally held that, of the two inorganic accelerators, litharge is more powerful than magnesia. My experience led me to question some of these statements, and I give the results of a number of vulcanising experiments with 90 parts of ordinary pale plantation crêpe rubber, 10 parts of sulphur, and small quantities of the following accelerators:—(1) litharge, (2) magnesia,² (3) isonitrosodimethylaniline (Ac. I), (4) a basic amino derivative (Ac. II). All the compounds were vulcanised in steam for one hour at 35 lb. pressure (138° C.). Portions of the vulcanised compounds were extracted for one week (say 40 hours) with boiling acetone in a special extractor,³ and the sulphur remaining in the rubber was estimated. In the case of the litharge compounded samples the specimen after extraction was placed in ether acidified with hydrochloric acid for a few hours to decompose the lead sulphide formed.⁴ A second treatment sufficed for the complete removal of the lead. The combined sulphur is given, calculated as a percentage on the raw rubber taken (coefficient of vulcanisation). Rings were also cut from the vulcanised compound and the load required to elongate the specimen to 9 times its original length was determined.⁵ The figures are the average of tests on five rings and give the load in terms of grms. per sq. mm. cross-sectional area.

(1) Litharge.		
% Accelerator.	Coefficient.	Load, grms. per sq. mm.
nil	1.26	237
0.1	1.25	244
0.25	1.27	248
0.5	1.37	282
0.8	1.75	370

(2) Magnesia.

0.45	2.62	—
0.90	3.42	—

There being insufficient of the original raw rubber for the litharge "mixings," which were made after the others, it was necessary to use another sample of crêpe for this purpose. The coefficient and load for this latter sample differed a little from those of the crêpe rubber used for the

FIG. 1.

other three experiments; thus, for the one hour cure a coefficient of 1.26 was obtained instead of 1.4 and a load of 237 instead of 152. This, however, does not affect the conclusions to be drawn from the experiments. The relationship between

the amount of accelerator used and the coefficient is shown in Fig. 1. The curves start at a zero obtained by subtracting the natural coefficient of the rubber from that found after adding the accelerator. The conclusions may be summarised as follows:—

(1) Of the inorganic accelerators, magnesia is much more powerful than litharge, particularly in small amounts.⁶ The form of the curves would, however, lead one to expect that in larger proportions litharge would tend to approach magnesia in accelerating power.⁷ The curve for magnesia is convex to the ordinate, that for litharge concave. The action of litharge is frequently complicated by the withdrawal of part of the sulphur which reacts with the lead. This, however, does not affect the present experiments owing to the large proportion of sulphur and small proportion of litharge in the "mixings."

(2) Magnesium oxide is more powerful than the organic accelerator Ac. II. (basic amino derivative) in all proportions up to at least 1% of accelerator on the rubber. It is also more powerful than the organic accelerator Ac. I. (nitrosodimethylaniline) in proportions up to about 0.6%. The graphs for the organic accelerators are almost straight lines in contrast to the strongly curved graph for the magnesia. Therefore the effect of

slightly curved, consequently we may conclude that the coefficient and load are approximately proportional within the limits of the experiment. The graph for the magnesia compound is appreciably curved and the load increases more rapidly the higher the coefficient. It is therefore evident that, with compounded rubbers, even those containing less than one per cent. of mineral or organic

FIG. 2.

increasing the proportion of the organic accelerators is similar in both cases but different from that of the magnesia which is also different from that of the litharge.

Fig 2 gives the loads at a constant elongation after subtracting the load of the control for each. These figures define the position of the stress-strain curve which has been used by some as an index of the degree or state of cure.

It will be seen that the graph for the organic accelerator is practically a straight line, as also is that for magnesia up to a certain point which corresponds to a coefficient of vulcanisation of about 3.7. It therefore appears that, when a magnesia compound is appreciably over-cured, it becomes rapidly harder and less distensible the higher the coefficient. This effect is not noted with the organic accelerator. The graph for the litharge is slightly curved and closely resembles that in Fig. 1. Fig. 3 gives the coefficients plotted against the loads. The graphs for the organic accelerator and litharge compounds are only

FIG. 3.

accelerators, the load is seldom if ever exactly proportional to the coefficient and consequently the estimation of the rate of cure cannot be safely based on the loads, that is to say, the stress-strain curves, without checking these against the coefficient of vulcanisation. Even small quantities of quite inert ingredients appreciably affect the load corresponding to the same coefficient. Thus, in some earlier experiments⁸ it was shown that $\frac{1}{2}\%$ of zinc oxide in a rubber and sulphur mixing decreased the extension for a given load by about 11%, while $\frac{1}{2}\%$ of talc increased the extension by about 9%. These changes were accompanied by little or no increase in the amount of combined sulphur. The experiments in this paper are confined to the effect of very small proportions of accelerators such as are used in practice in the case of the organic accelerators. Inorganic accelerators such as litharge and magnesia are often used in larger proportions which cause a considerable modification in the properties of the vulcanised rubber, apart from the accelerating effect.

¹⁰ D. Spence, *J. Ind. and Eng. Chem.*, 1918, **10**, 115.

¹¹ B. J. Eaton, *this Journal*, 1917, 1225.

¹² The precaution was taken to ignite the magnesium oxide shortly before incorporation with the rubber.

¹³ *Analyst*, 1913, **38**, 143.

¹⁴ In accordance with the author's method of estimating sulphur in combination with rubber (combined sulphur) in the presence of metallic sulphides and sulphates. *Analyst*, 1915, **40**, 275.

¹⁵ That is, load when the elongated specimen measures 9 units, the original length of the specimen—one unit.

¹⁶ This disproves Eaton's contention (this *J.*, 1917, 1225) that lead oxide is a more powerful accelerator than magnesia. Consequently Eaton's explanation of the effect of litharge on the stress-strain curves is inadequate. Otherwise magnesia should have obscured the difference between fast and slow vulcanising rubbers more completely than litharge.

The explanation I put forward is based on previous work (this *J.*, 1915, 521; 1916, 874), in which I showed that the effect of litharge is to withdraw the sulphur which would otherwise be available for vulcanising the rubber. Litharge therefore acts in a twofold capacity. Firstly, as an accelerator and secondly, by reducing the proportion of sulphur available for vulcanisation, it has a retarding action on the rate of vulcanisation of the compound. The retarding effect produced by a reduction in the percentage of sulphur is apparent from Eaton's own curves (this *J.*, 1916, 1049). Compare for

Instance the graphs 146A and 146C. The latter corresponds to a mixing where the sulphur has been reduced by one-half. The 2 and 5 hour curves for this mixing (146C) are not further apart than the curves for 1 and 1½ hours of the mixing 146A. Consequently, a difference of 3 hours in the mixing 146C produces no greater effect on the curves than a difference of 1 hour in the mixing 146A, that is to say, the rate of vulcanisation as shown by the stress-strain curves on which Eaton relies is reduced to one-twelfth by reducing the percentage of rubber in the mixing by one-half. In manufacturing practice, 5% of sulphur on the rubber is a much more usual proportion than 10% and, if the former had been taken as the basis for comparison of plantation rubbers, the apparent variation in rate of cure would only be approximately one-twelfth of the figures which have been obtained by Eaton and published as representative of plantation rubber.

In the same article a number of other statements are made by Eaton in reply to my criticisms. Some of these statements are sufficiently refuted by previously published work. Others will be dealt with by the publication of experimental evidence at a later date.

⁷These conclusions do not necessarily hold for dry-heat vulcanising.

⁸This Journal, 1911, 1421.

ON THE QUALITY OF GLYCERIN FROM WHALE OIL.

(A correction.)

BY A. H. SALWAY, D.S.C., PH.D.

In a recent communication (this J., 1918, 123 T) on the above subject an account was given of a method of investigating crude glycerin for the presence of trimethyleneglycol, and an approximate estimation of the amount of the latter was based on a determination of the specific gravity and apparent glycerol content, using the equations,

$$\begin{aligned} \text{sp. gr.} &= 1 + 0.00263x + 0.00053y \dots\dots\dots (1) \\ \text{apparent glycerol content} &= x + 0.81y \dots\dots\dots (2) \end{aligned}$$

where x and y are the percentages of true glycerol and trimethyleneglycol respectively.

The attention of the author has now been drawn to the fact that equation (1) is correct only when x and y are percentages by volume. In equation (2) x and y represent percentages by weight, and therefore the two equations cannot be used in conjunction for the calculation of x and y . Equation (1) should be:—

$$\text{Sp. gr.} = \frac{100}{\frac{x}{1.263} + \frac{y}{1.053} + (100 - x - y)} = \frac{100}{100 - 0.2082x - 0.0503y}$$

When this equation is used for the calculation of the trimethyleneglycol content of crude glycerin it is found that the figures previously given require modification to some extent. The general conclusions are not however affected. The table on p. 124 T should read:—

W hale oil.	Source of the glycerin.	Glycerol.	Trimethylene- glycol.
No.		%	%
0.....	Saponification process	85.0	nil
0.....	Autoclave	78.0	nil
2.....	Twitchell "	93.3	0.004
2.....	Autoclave "	80.0	0.01
3.....	Saponification "	77.5	0.01
4.....	Autoclave "	—	0.94

DEOXIDATION OF COPPER AND COPPER ALLOYS.

BY W. R. HODGKINSON, C.B.E.

In a paper read recently before the American Electro Chemical Society by G. F. Comstock (see this J., 1918, 210 A), reference was made to the use of zinc and silicon as deoxidisers in the production of copper castings. The object of the present note is to call attention to the valuable properties of calcium carbide in this respect (see this J., 1914, 445). A mixture of calcium carbide with borax or salt is a more efficient reducer of cuprous oxide in copper or its alloys than any of the deoxidising agents usually employed, and it has the additional advantage of leaving the brass or bronze free from carbon. In the treatment of cupro-nickel a small amount of carbon may be introduced into the metal, but this will not affect its use for most purposes.

The electrical conductivity of the metals is unaltered by the carbide process unless the carbide is very much contaminated with sulphide, which is seldom the case; even then, however, this may be counteracted by the use of borax in sufficient quantity. A flux which has proved entirely satisfactory consists of one mol. of carbide to two mols. of borax.

London Section.

Meeting held at Burlington House on Monday,
May 6th, 1918.

DR. CHARLES A. KEANE IN THE CHAIR.

THE INHIBITORY EFFECTS OF WATER ON THE INTERACTION OF ALUMINIUM AND (a) THE FATTY ACIDS; (b) PHENOL, CRESOL, α - AND β -NAPHTHOLS; (c) METHYL, ETHYL, BUTYL, AMYL, AND BENZYL ALCOHOLS.

BY RICHARD SELIGMAN AND PERCY WILLIAMS.

In a paper read before the London Section of the Society of Chemical Industry (Seligman and Williams, this J., 1916, 88) the action of a number of boiling, concentrated, lower fatty acids upon aluminium was described. It was shown that, whereas these acids when concentrated, in the ordinary sense of the word, were extremely inactive with regard to aluminium, yet, if entirely dehydrated and containing less than 0.05% of water, they rapidly attacked the metal.

Reference was also made to some preliminary experiments with a mixture of higher fatty acids, which appeared to show that these behaved like their lower homologues with respect to aluminium.

These experiments have been continued both with mixed acids and with preparations of "pure" palmitic and oleic acids, and there is now no room for doubt that these acids, in the absence of water, attack aluminium most vigorously, whilst minute traces of water suffice to inhibit the action entirely. If heated in air the higher fatty acids only attack aluminium at temperatures in the neighbourhood of 300°C., whereas if heated in a current of a dry neutral gas or *in vacuo*, interaction starts at very much lower temperatures. This is in all probability due to the fact that before attack by an acid heated in the air can commence, conditions must obtain in which the water produced by the oxidation of the acid is eliminated as rapidly as it is formed, and this is the case at high temperatures. As in the case of the lower acids, a current of an indifferent dry gas has been found most efficacious in removing traces of moisture, and so enabling the interaction to start at lower temperatures, but a current of oxygen protects the metal from attack. This is due to the fact that water is produced by contact of oxygen with the higher acids, whereas the lower acids previously experimented with are not oxidised under the conditions prevailing.

With the conclusion of these experiments certain cases which have occurred in practice in which aluminium has been attacked by higher fatty acids have been satisfactorily explained, and the course or courses to be followed in order to obviate their recurrence have been indicated. Experiments have shown that the composition and physical state of the metal are not without bearing upon the rate of attack, but a definite statement on this point would be premature.

The causes which determine the action of fatty acids upon aluminium having been thus elucidated, an analogous explanation was sought in the case of phenol and similar substances. Numerous attempts have been made to use aluminium stills and condensers for refining phenol and cresol, for which purpose the metal seemed to be particularly suited owing to its cleanliness and the fact that no

discoloration of the refined products was to be feared. The attempts have, however, failed owing to the fact that at high temperatures, which seemed to be quite definite for each substance, the phenols attack aluminium very rapidly. Gladstone and Tribe, as well as Cook, have investigated the interaction of various phenolic substances and aluminium. Gladstone and Tribe (J. Chem. Soc., 1881, 39, 9-19, and 1882, 41, 155-156) state that boiling phenol and cresol attack aluminium very slowly, and β -naphthol "is acted on between its melting and boiling points," but that thymol, benzyl alcohol, and α -naphthol are not acted on at all except in the presence of aluminium iodide. Cook (J. Amer. Chem. Soc., 1906, 28, 608, and Amer. Chem. J., 36, 543) states that "when commercial aluminium and pure phenol are heated sharply for 2 or 3 hours a violent reaction sets up, precisely the same as in the other methods" (i.e., use of aluminium iodide). In the case of *m*-cresol Cook found that the interaction might be started at the boiling point. In both cases he found that the addition of a small amount of the aluminium compound promoted the attack. He also concluded that "the action of aluminium on phenol is electrolytic in character," and to explain the difference between his results and those of Gladstone and Tribe he suggested that the metal used by the latter was much purer than "the modern commercial article" used in his own experiments. He states that "for the reason that a very pure aluminium would not contain sufficient impurities to set up local action it would be without action upon phenols unless a catalytic agent like iodine should be employed." Experiments made with phenol, cresol, β -naphthol, and α -naphthol have disproved most of these views, as well as that long held that critical temperatures existed for phenol and cresol respectively, below which interaction did not take place. The first experiments conducted with boiling aqueous solutions of phenol showed that such solutions were for all practical purposes without action upon aluminium,* and that the same inactivity prevailed in the case of solutions of small quantities of water in pure phenol. Thus, for instance, a sample of aluminium boiled for 2 hours in pure phenol, mixed with a small quantity of water under conditions which precluded the escape of the water, remained entirely unchanged. When, however, the phenol was dehydrated violent action immediately set in. Moreover, the action once started continued even if the temperature was lowered to close to 50°C. As in the case of the fatty acids, it was found possible to inhibit the action altogether by the addition of small quantities of water, no attack taking place when the phenol contained as little as 1% of water.

Similar conditions were found to prevail with regard to a mixture of the cresols and to α - and β -naphthol, all of which, when anhydrous, attack aluminium violently, although α -naphthol acts with less readiness than the other substances. It was, however, found more difficult to stop the attack by these substances when once started than in the case of the lower fatty acids, possibly because of their higher boiling points and the consequent difficulty of securing intimate admixture of the water added, but probably also because the rate of attack is very rapid, and consequently much aluminium phenoxide is formed, which entails the addition of considerable quantities of water before complete decomposition can be brought about. The dissolved phenoxides, etc.,

* If left in contact with aluminium for many months in the cold in the presence of air these solutions attack aluminium in much the same way as water does.

thus tend to keep the phenols anhydrous and so allow the interaction to proceed. These properties also explain the fact observed by Cook that the commencement of the interaction is hastened by the presence of the aluminium compounds. It has been found incidentally that the interaction of the phenoxides and water takes place in at least two stages, the first substance formed being soluble in certain dry organic solvents. The addition of further quantities of water brings about complete decomposition into the phenol and aluminium hydroxide, as described by Cook (*loc. cit.*).

The composition of the metal has been found to affect the rate of attack, but in the opposite sense to that suggested by Cook.

The experiments made with phenol and similar monohydroxy compounds were repeated with various dihydroxy compounds, such as quinol and resorcinol, and the trihydroxybenzene, pyrogallol. With none of these could interaction be brought about by any of the methods used. At this point it is desirable to anticipate somewhat, and to say that similar negative results were obtained with polyhydroxy alcohols such as glycol and glycerol. It may be suggested that the failure of these polyhydroxy compounds to attack aluminium is due to their partial decomposition by which sufficient water is formed to inhibit the interaction. Against this view must be cited the fact that Gladstone and Tribe, using iodine as a catalyst, also failed to form the aluminium compounds of glycol and glycerol, and that similar negative results attended the experiments with amalgamated aluminium on glycols recorded by Tischitschenko (*J. Russ. Phys. Chem. Soc.*, **31**, 694—770 and 784—872; *Jahresber.*, 1899, 871). During the course of the present experiments all the polyhydroxy compounds referred to above have been subjected to the action of amalgamated aluminium under various conditions of temperature and dehydration, and although occasional indications of possible incipient attack were noted, it is not considered that these were sufficiently definite to refute the view that no interaction between them and aluminium takes place.

In reading the account of Gladstone and Tribe's experiments it was seen that the device of drying a liquid by a current of hydrogen used by the present authors with acetic acid, etc., had, although unknown to them, been applied to the dehydration of glycerol (*J. Chem. Soc.*, 1881, **39**, 31). It is interesting to consider that had Gladstone and Tribe applied the same device to the other alcohols they worked with they would have found the use of iodine unnecessary.

During recent years aluminium has been used on a considerable scale for the manufacture of vessels for the acetylation of various alcohols. From time to time cases have occurred in which these vessels have been attacked. It has been impossible to explain this (*cf.* Boake, this *J.*, 1917, 414), especially in view of the fact that other vessels, apparently identical in construction and composition and similarly used, have not suffered. With the knowledge available of the protection afforded by minute quantities of water the action of anhydrous alcohols upon aluminium was investigated.

It has been known for a long time that aluminium which has been amalgamated with mercuric chloride dissolves in alcohol with the formation of aluminium ethoxide. It has been assumed, however, that the alcohols would not attack the unamalgamated metal. [Meyer and Jacobsen (*Lehrb. der organ. Chem.*, 1907, 212) say that "pure aluminium is only very slowly attacked by boiling ethyl alcohol." This obviously does not refer to conditions such as are about to be described.] Thus Gladstone and Tribe (*J.*

Chem. Soc., 1876, 153) say "ethyl alcohol was found to have no effect on aluminium alone even when boiled with it for some hours." These authors also experimented with propyl, iso-butyl, amyl, cetyl, and allyl alcohols, whilst reference has already been made (*loc. cit.*) to the negative results of their experiments with benzyl alcohol.

The experiments described in this paper have shown conclusively that where the alcohols can be sufficiently dehydrated they attack aluminium, some of them with extreme readiness, and the form which the attack takes leaves little doubt that herein is to be sought the explanation of the cases of corrosion referred to above. Methyl, ethyl, normal butyl, amyl, and benzyl alcohols when sufficiently anhydrous attack the metal at high temperatures. As in the case of the fatty acids, minute quantities of water are sufficient to prevent the attack or to stop it when once started. The conditions governing sufficient dehydration vary with the different alcohols. Thus amyl and butyl alcohols can be dehydrated by simple boiling in a deep tube and allowing a small fraction to distil off. The alcohols so treated rapidly attack aluminium, and indeed this seems to be a more convenient method of preparing the alkyloxides than that requiring the amalgamation of the metal. In the case of ethyl alcohol this method gave no hope of success, but the desired end was attained by distilling a mixture of 99.5% alcohol with benzene, the water passing over in the earlier fractions in the form of a ternary mixture (*cf.* Young, *J. Chem. Soc.*, 1902, **34**, 708). In this way ethyl alcohol was so far dehydrated that interaction with aluminium could be brought about, but the method was not convenient. By distilling ethyl alcohol over calcium and taking precautions to avoid the introduction of moist air into the receiver adequate dehydration was accomplished, and the alcohol so prepared readily attacked the metal. Still greater difficulty was experienced in the case of methyl alcohol. It is interesting to note that Gladstone and Tribe (*loc. cit.*) failed to obtain aluminium methoxide by the method which gave them the aluminium compounds of other alcohols, namely by interaction in the presence of aluminium iodide, a fact which they attributed to the "unstable character of the methylate." The present experiments have, however, shown that by the most meticulous care in the exclusion of water direct interaction of aluminium and methyl alcohol may be brought about. The rate of attack is, however, very slow, a fact which may possibly be due to the slight solubility of the methoxide in methyl alcohol.

As in the case of the fatty acids, the composition and state of the aluminium appear to influence to some extent the rate of attack by anhydrous alcohols.

In the paper referred to above, in which attention was first drawn to the interaction between aluminium and anhydrous fatty acids (*loc. cit.*, p. 89) two hypotheses were raised to explain the inhibition exercised by minute traces of water upon the interaction. It was suggested that acids containing small quantities of water were inactive towards aluminium on account of the formation of a continuous gelatinous, and therefore protective, coating of basic salt upon the surface of the metal, whereas in the absence of water the product of the interaction, being crystalline, would be discontinuous and therefore not protective. That all action ceased as soon as a trace of water was added would then be due to the fact that the crystalline salt formed was incapable of existence in the presence of water. As an alternative, the view was advanced that the rate of dissolution of aluminium in fatty acids is normally very high, but that whenever water is present the

metal becomes coated with the well-known film of oxide which protects it.

As a result of the experiments described in the present paper a combination of these two hypotheses seems to be called for. The view now advanced is that the metal is normally protected by the film which covers it, but that this film breaks down when exposed to the attack of the dehydrated substances experimented with. The presence of even the minutest traces of water in excess is sufficient to inhibit the attack owing either to the fact that the salts, phenoxides, or alkyl oxides, as the case may be, are immediately decomposed by water, aluminium hydroxide being formed, which is insoluble, or because the aluminium exposed by the breakdown of the film is immediately re-oxidised by the water. In one case ocular evidence in support of this view was obtained. A strip of aluminium was boiled with some dehydrated butyl alcohol, solution taking place at a single point from which a fine stream of hydrogen bubbles was evolved. Water to the amount of 0.04% of the alcohol was introduced by means of a capillary tube. Within a few minutes the stream of bubbles ceased and the point from which they had been evolved was seen to be coated over by a minute film, presumably of aluminium hydroxide. This hypothesis would, however, demand the gradual though probably extremely slow consumption of the water and the ultimate cessation of its inhibitive action. On this point there is at present neither negative nor positive evidence.

The extreme sensitiveness of the compounds formed to water and their resulting dehydrating tendency appear to explain the fact that the interaction increases in violence as the products of the attack accumulate. It has been observed that the number of points at which the metal is attacked is much larger when the proportion of metal to solvent is large, and consequently the metal content of the solution high, than when small pieces of metal are exposed to the attack of large quantities of solvent. Moreover, the attack by these liquids containing large quantities of metal dissolved cannot be stopped by traces of water. No doubt the bulk of the compound must be decomposed with the production of hydroxide before the water becomes operative in this respect.

EXPERIMENTAL.

Higher fatty acids.

I. A mixture of higher fatty acids was used, the composition of which was palmitic acid 55%, stearic acid 40%, oleic acid 5%. The aluminium was in the form of sheet 0.5 mm. thick, and its composition was Si 0.13, Fe 0.14, Cu 0.00, Al 99.73%. Before the experiment it was cleaned with dilute caustic soda, as described in the previous paper. Two forms of apparatus were used, according to whether it was intended that the experiment should be conducted in the air or in one or other of the gases experimented with. In the first case the apparatus consisted of a narrow, deep boiling tube, with a small side tube close to the open top. A thermometer dipped into the contents of the tube and the whole was suspended inside a wider tube above a small quantity of boiling bromonaphthalene. For temperatures above 280° C. the outer tube was replaced by a sand bath. Where it was desired to pass a dry gas through the system the boiling tube was closed by a cork, through which passed a glass tube closed at its upper end by a cork through which a thermometer passed into the liquid. At its upper end this tube was, like the boiling tube, supplied with a side tube. Both side tubes were connected to U-tubes containing concentrated sulphuric acid, and the upper U-tube was in its

turn connected with the source of the gas experimented with.

The results obtained may best be indicated in tabular form.

TABLE I.

Temperature	Atmosphere			Vacuum (15 mm.)
	Air (open tube)	Dry hydrogen	Dry nitrogen.	
300°-310° C.	Attack with- in 5 min. of introduction of metal			
280° C. ...	Results regular	ir- Rapid attack immediately on intro- ducing metal		
250° C. ...	No attack in 7 hours	Attack with- in 5 min.	Attack with- in 5 min.	
227° C. ...				Residual at- mosphere air, attack commenced within 30 min.
200° C. ...		Attack with- in 1 hour of introduction of metal		
155° C. ...				Residual at- mosphere air, very slight at- tack during 3 hrs. Re- sidual atmo- sphere hy- drogen, at- tack within 30 min.

In the case of the experiments in air, the formation of a considerable amount of water was observed which at temperatures of 300° C. and above rapidly escaped from the tube, whereas at 250° C. the water formed remained in the tube.

II. *Palmitic acid*, bought as "acid palmitic pure," was used in these experiments, which were carried out with the same metal and in the same apparatus as already described. The results are shown in Table II.

TABLE II.

Temperature	Atmosphere	
	Air (open tube)	Dry hydrogen
300°-310° C. ...	Attack within 5 min. of introduction of sample	
270° C. ...	No attack 1½ hours	
250° C. ...	No attack 1½ hours	Attack within 10 min.
200° C. ...		Slow attack within 1 hour

III. *Oleic acid* bought as "acid oleic pale" was used in this series of experiments. The other conditions were the same as before. The results are tabulated below.

TABLE III.

Temperature	Atmosphere	
	Air (open tube)	Dry hydrogen
300°-310° C....	Immediate and rapid attack	
250° C.	No attack during 7 hours	Rapid attack within 15 min.
200° C.		Slow attack within 20 min.

Phenol, Cresol, and Naphthol.

Phenol. The aluminium used was of the same composition and form as in the experiments already described.

A weighed strip of aluminium was heated with a solution of phenol boiling at 113° C. (uncorr.) in a boiling tube covered with a watch glass. After the heating had been maintained for an hour the metal was re-weighed, but no loss of weight could be detected. The strip was replaced in the tube and the heating continued, but without the cover glass. The boiling point of the phenol solution gradually rose until it reached 177° C. (uncorr.), when rapid attack of the metal commenced.

A further quantity of the phenol solution was heated in the uncovered tube without any aluminium until the boiling point reached 180.5° C. (uncorr.). On introducing a strip of aluminium into the boiling liquid immediate solution of the metal commenced.

In order to make certain that the facts recorded above were not primarily due to temperature, two strips of aluminium were heated with phenol in sealed tubes. The tubes contained phenol which had been dehydrated by heating in a current of dry hydrogen, but to one tube a quantity of water equal to about 1% of the phenol used was added. The tubes were immersed in a vapour bath of boiling phenol. Immediate attack was observed in the case of the tube containing the dry phenol, and on removing the tube from the vapour bath solution of the metal continued so long as the phenol remained liquid. No attack of any kind took place in the tube to which water had been added.

Further experiments with dehydrated phenol. In addition to boiling in an open tube, phenol was dehydrated by boiling in a current of dry hydrogen. On placing a strip of aluminium in the boiling anhydrous material, the current of dry hydrogen being maintained, attack commenced within a few minutes and rapidly became most energetic. At a temperature of 128° C. attack developed immediately upon the introduction of a strip of the metal but was relatively slow and showed little acceleration during 20 minutes. At 80° C. slight attack commenced within 80 minutes, and on the phenol being allowed to cool continued until solidification occurred.

Effect of the addition of water to solutions of aluminium in phenol. The experiments so far described show that phenol containing aluminium in solution attacks the metal rapidly. These solutions remain clear while hot, but on cooling become cloudy at temperatures well above the freezing point of phenol. They become clear again if the temperature be raised. On the addition of a small quantity of water to such solutions a dense white solid separates, which was found to be insoluble even in boiling phenol and also

in boiling toluene, but readily soluble in boiling dry butyl alcohol. On addition of water to the butyl alcohol solution it was decomposed, aluminium hydroxide being precipitated. Hot phenol containing this solid in suspension was found to attack aluminium readily. On the addition of more water the precipitate changed into a gelatinous mass, similar in all respects to aluminium hydroxide. The phenol now no longer attacked aluminium until it had been dehydrated afresh by heating for several hours in a current of dry hydrogen. Quantitative experiments were not made.

Experiments showed that phenol dissolved in a boiling indifferent substance, such as naphthalene, rapidly attacked aluminium in the absence of water.

Cresol. A mixture of cresols, bought as "cresylic acid pure," was used. The experiments were the same as with phenol and gave identical results, except that owing to the cresol being liquid the action of the dehydrated material could be followed during cooling to normal temperature. On adding water to a solution of aluminium in cresylic acid a further difference was noted in that the first product of the interaction was soluble in boiling cresylic acid, whereas the corresponding phenol compound was not soluble in phenol.

Naphthol. Gladstone and Tribe (*loc. cit.*, J. Chem. Soc., 1882, 41, 5) state that α - and β -naphthols differ with regard to aluminium in that the latter attacks the metal whereas addition of iodine is necessary in order to bring about action by the α -compound. Experiments were therefore made with both α - and β -naphthols, and both were found to attack aluminium in a manner similar to the other hydroxy-compounds examined, but the rate and form of attack varied as between the two compounds.

β -Naphthol. At the boiling point β -naphthol was found to attack aluminium extremely vigorously, a strip of metal being dissolved in a few minutes. At 185° C. no attack took place during the course of an hour when a little water was present, but on passing a current of dry hydrogen through the heated liquid a strip of the metal subsequently introduced was rapidly attacked. At 125° C. no attack took place during 2 hours, even in a current of dry hydrogen.

Boiling naphthalene containing 10% of β -naphthol attacked aluminium within 10 minutes of its introduction into the liquid.

α -Naphthol. The material used was bought as a "Nobel's standard chemical." It melted at 93.7° C., and gave no ash on ignition. A small quantity was freed from water either by boiling in an open tube or by boiling in a current of dry hydrogen. On boiling α -naphthol so treated it was found to attack aluminium slowly. The attack was intensely local and on many occasions only took place at one point. In some cases where attack had started at a number of points, all but one point suddenly ceased to give off gas, attack then proceeding much more rapidly at the remaining point. At 185° C. attack was very slow, whilst a boiling solution of α -naphthol in naphthalene did not attack the metal at all during the course of an hour.

In view of the negative results obtained by Gladstone and Tribe it was thought that the attack might be due to the presence of small quantities of β -naphthol. The α -naphthol was therefore re-crystallised, but no difference in the behaviour of the purified substance was observed.

In order to make certain that the attack observed was due to α -naphthol, an amount of aluminium sufficient to saturate 35% of the naphthol used was dissolved in the boiling liquid, by which means

it was safe to assume that any β -naphthol present would be neutralised. The liquid so prepared was found to attack aluminium as before.

Alcohols.

Butyl alcohol. Pure, normal butyl alcohol containing about 1% of water was used. A strip of aluminium was boiled with this alcohol under conditions designed to preclude the escape of the water. During 3 hours no interaction could be detected. The apparatus was then opened so as to allow the aqueous fraction of lower boiling point to escape. Under these conditions attack commenced within 5 minutes. The rate of attack rapidly increased until the heat developed caused the contents of the tube to boil over. On cooling, solid aluminium butoxide separated from solution.

During a further experiment in the closed apparatus it was noticed that after two hours' boiling interaction started at a single point owing, it was assumed, to the condensation of the small aqueous fraction in the cooler parts of the tube or its accidental escape. When a quantity of water equivalent to 0.04% of the alcohol was added, the stream of gas bubbles flowing from the point of attack ceased within 5 minutes and the point itself was seen to be covered by a flocculent pellicle, presumably of aluminium hydroxide. After a further two hours' boiling attack again commenced at a single point, and was again arrested in the same way. On opening the tube and boiling off the aqueous fraction vigorous action started within 3 minutes.

After the interaction had proceeded for some time and a considerable quantity of aluminium had passed into solution, small quantities of water no longer sufficed to arrest the attack, a definite quantity being first required to decompose the butoxide formed. Similarly it was found that butyl alcohol containing the butoxide in solution attacked the metal with greater vigour and rapidity than the fresh alcohol. From this observation it followed, and was confirmed by experiment, that the rate and form of attack were dependent upon the relative volume of the alcohol to the surface of the metal exposed to attack, since the amount of aluminium dissolved in a small volume would be proportionately greater than in a large volume. It was found that butyl alcohol which had been thoroughly dehydrated attacked aluminium when boiling under a reduced pressure equivalent to 150 mm. of mercury.

Amyl alcohol. The material used was bought as "amyl alcohol purified for milk analysis." It was found to be similar in all respects to butyl alcohol with respect to its action upon aluminium, but to attack the metal less vigorously. Attack could be arrested by the addition of 0.04% of water.

Ethyl alcohol. The alcohol used was bought as "absolute alcohol 99.5%." On boiling this with a strip of aluminium for 3 hours neither evolution of gas from the surface of the metal nor change in weight of the latter was observed.

Experiments with dehydrated alcohol. (a) *Dehydration by distillation with benzol* (cf. Young, *loc. cit.*). 8 c.c. of 99.5% alcohol, 8 c.c. of dry benzol, and a strip of aluminium were boiled together, 8 c.c. of the mixture being distilled off. A further 8 c.c. of benzol was then added and the distillation continued. When the volume of the liquid had been reduced to 4 c.c. it was found that slight attack took place wherever the surface of the metal was scratched.

(b) *Dehydration by distillation over calcium.* The apparatus used consisted of a 100 c.c. conical flask having a cork stopper fitted with a comparatively wide vertical glass tube about twice

the depth of the flask to serve as a spray trap. The top of this still-head communicated by glass tubing with a boiling tube of the form used throughout these experiments. The side tubulure of the boiling tube was connected to a U-tube filled with glass beads and sulphuric acid. 30 c.c. of alcohol and 3 grms. of calcium were placed in the conical flask. When evolution of hydrogen had ceased about 8 c.c. of the alcohol was distilled over on to a strip of aluminium which had been placed in the boiling tube, and the conical flask and tubing then disconnected and the boiling tube rapidly stoppered. The alcohol in the boiling tube was then heated to boiling point. Within a few minutes evolution of gas was observed from one point, other points of attack developing as the experiment was continued.

The alcohol, which, at the end of the experiment, contained a considerable quantity of aluminium in solution, remained clear. On distilling off the liquid over a water-bath a solid residue remained, which proved to be volatile when heated under reduced pressure, and may therefore be assumed to have been aluminium ethoxide.

Methyl alcohol. The methyl alcohol used was bought as "methyl alcohol free from acetone." It was dehydrated in the same way and in the same apparatus as used for the dehydration of ethyl alcohol, but repeated attempts to induce attack proved abortive. The addition of metallic calcium to a tube containing aluminium and dehydrated alcohol also failed to cause attack on the aluminium even when heating was maintained for 8 hours. It was thought that the low boiling point of methyl alcohol might possibly account for the absence of attack, and in order to eliminate this condition experiments were made in sealed tubes. These experiments led to positive results, although temperature is not the governing condition. On the other hand, it was found that the interaction in the case of methyl alcohol is so sensitive to traces of water that only in sealed tubes could a sufficient degree of dehydration be accomplished to enable attack to start.

The first experiment made in sealed tubes was so designed that any water in the alcohol or which might be produced or introduced during sealing of the tube should be taken up by a methoxide which was present in excess. Various attempts were made to use aluminium methoxide for this purpose, but as the only known method of preparing this compound depends upon the presence of mercury, and as it was found extremely difficult to ensure the complete subsequent removal of the mercury, calcium methoxide, which can be prepared by direct interaction of calcium and methyl alcohol, was used. 5 c.c. of methyl alcohol (freshly distilled over calcium), 0.5 gm. of calcium, and a weighed strip of aluminium were placed in a glass tube, the open end of which was then drawn out to a fine capillary and connected to a drying tube (the glass tube used for all sealed tube experiments was boiled with hydrochloric acid in order to remove all traces of alkali). When evolution of hydrogen had entirely ceased, the tube was sealed off and placed in a vapour bath of ethyl alcohol. Under these conditions it was assumed that any traces of water present would be absorbed, and in point of fact minute corrosion of the aluminium and a loss of weight of 0.0028 gm. were observed when the heating had been maintained for 8 hours. Practically identical results were obtained at 100° C. using a steam bath, and at 66° C. using a bath of methyl alcohol vapour, thus showing that temperature was not of determinative importance.

It was thought desirable to obtain similar results in the absence of calcium or calcium methoxide, although it is extremely improbable

that these could play any part other than that of dehydrating agents.

A preliminary experiment showed that 99.5% methyl alcohol, when heated at 100° C. for 8 hours in a sealed tube with aluminium, did not attack the metal.

The experiment made with ethyl alcohol distilled over calcium had already been repeated with methyl alcohol and had given negative results, and sealing off the receiver when the methyl alcohol had been distilled into it similarly failed. This last failure was ascribed to the formation of water during sealing, and the following arrangement, which proved effective, was adopted to obviate this difficulty. The receiver having been thoroughly dried, about 5 c.c. of methyl alcohol was distilled over calcium on to a strip of aluminium. The receiver was then immersed in a freezing mixture to reduce the vapour pressure of the alcohol, and a current of dry hydrogen passed through the upper part of the tube, which had already been drawn out to a capillary. Under these conditions the capillary was sealed off. On immersing the tube in a vapour bath of methyl alcohol attack started within 1 hour, and continued, though very slowly, for 8 hours, when only 0.0002 grm. of aluminium was found to have been dissolved. At each point of attack a minute rod of a white solid was formed, which was subsequently found to be soluble in butyl alcohol and to yield aluminium hydroxide in contact with water. On removing the tube from the vapour bath the reaction stopped, but restarted when heating was resumed. At 100° C. no increase in the rate of attack was noticeable.

Benzyl alcohol. Benzyl alcohol was found to mark in some respects a transition stage between ethyl alcohol and butyl alcohol in that, whereas it was much more readily dehydrated than the former, it was more difficult to render absolute than the latter. Its action on aluminium was, however, found to be entirely analogous to that of the other alcohols. A complication was introduced by the well-known propensity of this alcohol to undergo autooxidation, whereby sufficient water is formed to inhibit the interaction under investigation.

On boiling a sample of the alcohol in a long, narrow tube in such a way that the fractions of lower boiling point condensed in the upper parts and thence flowed back again, no attack was observed during the course of an hour. On repeating this experiment in a shorter and wider tube from which the aqueous fraction could escape, the alcohol rapidly became anhydrous and in this condition freely attacked the metal. Similarly on passing a current of dry hydrogen through the liquid which was being boiled in the narrow tube, attack developed as with the other alcohols examined. On replacing the current of dry hydrogen by a current of the same gas which had passed over glass beads moistened with water, a precipitate of aluminium hydroxide was gradually formed, and after this had apparently become complete the alcohol no longer attacked the metal.

It was found possible to dehydrate benzyl alcohol in a stream of dry hydrogen and to render it active with regard to aluminium at temperatures of 185° and 128° C.

Experiments in sealed tubes were made with benzyl alcohol. On heating the alcohol in its original form with aluminium in a sealed tube for 2 hours at 220° C. no signs of attack were observed. The same experiment made with a sample of the alcohol dehydrated by being boiled in a current of dry hydrogen also gave negative results. It was assumed that sufficient water had been produced by the oxidation of the alcohol during the sealing of the tube to inhibit the interaction, and the experiment was therefore

repeated with the modification that the tube was exhausted before sealing and sealed under vacuum. On heating the tube to about 200° C. attack commenced and continued after the contents of the tube had reached normal temperature.

DISCUSSION.

The CHAIRMAN asked what degree of dehydration the authors had been able to secure in the case of phenol and the other hydroxylic compounds. In his own experience it was only by means of very special precautions that really anhydrous phenol could be obtained, and as one regarded a third substance, such as water in this case, as an essential agent for reactivity rather than as a deterrent, it would be of interest to know whether it was really excluded. He also asked whether the experiments had been carried out in the presence or absence of air, as possible oxidation by air might be a contributory cause to the reactivity with the aluminium.

Mr. T. H. DURRANS asked whether the authors had studied the action of acetic anhydride on aluminium, and also whether they had made a microscopical examination of the aluminium, because the samples exhibited were perfectly bright and there was no evidence to the eye of any protective film being formed.

Dr. A. F. JOSEPH asked whether the sensitivity of the reaction bore any relation to the quantity of water present.

Mr. C. E. BARRS asked whether the standard of purity of the aluminium had been the same throughout the whole of the experiments.

Mr. H. TALBOT said that in endeavouring to explain why aluminium was or was not attacked the authors had put forward the idea of a protecting layer on the surface of the metal, but they had not given a very clear notion as to whether it was aluminium oxide, hydroxide, or other aluminium compound, or a state of the aluminium. Was the layer material, or was it simply a state of the aluminium? If the former, what was its composition; if the latter, how could it be produced, how could it be altered, and how could it be recognised microscopically?

Dr. SELIGMAN, in reply to the Chairman, said that they did not pretend to have decided the actual degree of dehydration of material that had been obtained; the experiments had been based on severely practical requirements. They did not pretend in any way to have obtained dryness in the sense of the word used in Prof. Baker's communications. They only knew that extremely small additional quantities of water were sufficient to stop this reaction. For instance in the case of methyl alcohol, leaving the end of a tube which had been drawn out to a capillary open for a short time allowed enough water to get in to stop the interaction. He did not know the purity of the phenol used, which was bought as pure phenol. In view, however, of the fact that all the materials that had been experimented with attacked aluminium in the same way, was not it unlikely that in every case they should contain the same impurity? Moreover, in the experiments with lower fatty acids prolonged search had been made for impurities responsible for the phenomenon observed, but without any positive result. In connection with their previous paper the Chairman had suggested one or two possible causes for the attack, amongst them being the formation of aldehyde. That had been investigated and they had found that aldehyde played no part in the interaction. It had been impossible to trace anything responsible for the reaction and they had been faced with the fact, which as the Chairman had pointed out was a most surprising one, that far from water facilitating the reaction, as they had supposed would be the

case, the more the water was removed the more rapid was the attack. These experiments had been tried in the presence of air and they had also been made in hydrogen, in nitrogen, and in *vacuo*, and the same results were found in every case. In regard to the effect of acetic anhydride on aluminium, the pure anhydride would probably be without effect, but it was impossible to obtain it unmixt with acetic acid, and a mixture of acetic acid and acetic anhydride gave anhydrous acetic acid, which produced the conditions which were being discussed. In reply to Mr. Durrans, no protective film could be seen on aluminium by the eye, neither could it on any cooking pan, and yet those who had to deal with aluminium were all quite satisfied that it was there. The standard of purity of the metal in these experiments, except where it was varied to see the effect, had been the same, 99.7%. The Chairman had suggested that possibly impurities might account for the trouble, but the purer the metal the more rapidly it was attacked. That was another curious fact which he left to be explained. With regard to Mr. Talbot's question, he had already expressed his view as to the existence of the protective film, but he had no knowledge as to its composition except that it was generally assumed to be a colloidal hydroxide of the metal. As to its visibility he hesitated to say except that in watching molten metal being poured from a crucible or a furnace he had always been struck with the fact that one saw at certain temperatures an apparently perfectly fluid metallic surface, and at certain moments that surface was covered over by a film, but nothing of the film could be seen after the metal had solidified. That he believed was the only actual tangible and ocular evidence of the existence of the film except that aluminium had to be rubbed somewhat vigorously in order to get good electrical contact.

HOT WIRE ANEMOMETRY: ITS PRINCIPLES AND APPLICATIONS.

BY J. S. G. THOMAS.

When the velocity of a gas current has to be determined the usual method employed consists in the use of a Pitot tube and a sensitive tilting gauge. The Pitot tube and gauge measure the difference between the dynamic and static heads, and very approximately this difference of pressure is proportional to the square of the velocity of the gas current. In the hands of a skilled experimenter the tilting water gauge is capable of yielding accurate results, but is an instrument which cannot be placed with any degree of confidence in the hands of one unskilled in its use. Apart from this objection to the use of the Pitot tube for general works' purposes, there are certain points connected with the use of the Pitot tube which, in the opinion of some experimenters, make it questionable as to how far its indications are reliable in various circumstances. These objections to the use of the Pitot tube have been very succinctly summarised by Professor J. T. Morris.¹

The system of anemometry with which this paper deals, depends upon the cooling experienced by a heated wire when immersed in a stream of fluid. The theoretical aspects of the problem have been considered by Fourier,² Poisson,³ Boussinesq,⁴ and H. A. Wilson.⁵ Experimental work on the sub-

ject of the convection of heat from a heated wire has been carried out, amongst others, by Kennelly and Sanborn.⁶ Complete references to experiments on the subject have been published by Langmuir.⁷ Kennelly⁸ appears to have been the first to suggest that a measurement of the current required to keep a wire at a definite temperature when immersed in a current of air might be used as a means of determining the velocity of the air current. Kennelly, Wright, and Van Bylevelt enunciated the laws of cooling of heated wires in a stream of fluid as follows:—(1) The linear convection is proportional to the temperature elevation of the wire at the same wind velocity; (2) under varying wind velocities (200 to 2000 cm. per sec.) the linear convection increases as the square root of the wind velocity.

The subject was developed independently by Morris⁹ and by Bordini.¹⁰ An integrating form of anemometer has been described by Gerdien,¹¹ and the principle of electric heating of a gas has been employed by C. C. Thomas¹² in his electric gas meter. Experiments in hot wire anemometry were carried out by G. A. Shakespear in 1902. An exhaustive study of the subject has been made by L. V. King,¹³ who has succeeded in placing hot wire anemometry on an absolute basis, i.e., he has shown how it is possible to calibrate an anemometer wire in terms of its diameter and thermometric constants, independently of the use of any other wind-measuring instrument.

As has been stated above, hot wire anemometry is based on the cooling effect experienced by a heated wire when immersed in a stream of gas at some lower temperature. The laws determining this cooling effect, its dependence upon the temperature to which the wire is heated, its dependence upon the velocity of the gas stream and upon all the other factors involved, amongst others the emissivity of the wire, the thermal conductivity of the gas, etc., have been thoroughly studied. Practical hot wire anemometry, then, simply requires some method of determining the cooling effect of the gas stream upon the heated wire. Various methods are available and have been suggested and employed by different experimenters.¹⁴ In some cases the temperature of the wire is maintained unaltered, extra current being passed through the wire to compensate for the cooling effect of the gas stream. This is the method employed by King.¹⁵ The platinum wire is inserted in one arm of a Kelvin double bridge, the balancing resistance being composed of manganin, which possesses a negligible temperature coefficient. The pairs of ratio arms of the bridge are so adjusted that a balance can be obtained independently of all connecting or contact resistances. The wire is mounted at the ends of a fork, the tension of the wire being adjusted by means of a fine thread. The pairs of ratio arms are separately adjusted to equality, the bridge being thus balanced when the resistance of the anemometer wire is equal to that of the manganin wire. On inserting the anemometer wire in a stream of fluid, the bridge being balanced before insertion, the cooling of the anemometer wire by

the stream upsets the balance, and an adjustment of current through the anemometer wire is made by means of a rheostat until the bridge is again balanced. King has shown that the velocity, V , of the stream is related to the current, i , necessary to restore the balance by the equation $i^2 = i_0^2 + K \sqrt{V}$; when $V = 0$, $i = i_0$, so that i_0 is the current which produces a balance of the bridge in a still atmosphere. Platinum wire of 2.5 or 3 mils in diameter is found most suitable, that used in platinum thermometry being especially suitable. The wires for use as anemometer wires are calibrated by being whirled round at the end of a rotating arm. In this manner King has shown that the relation $i^2 = i_0^2 + K \sqrt{V}$ holds rigidly over the range from 17 to 800 cm. per sec., and certain results indicate that it holds over a much more extended range. At low velocities free convection currents from the wire may become sensible, altering the resultant direction of the stream past the wire, but this error can be eliminated if the wire is calibrated suitably disposed in the stream. Using a 3 mil wire an accuracy of 1% can be obtained in the determination of a velocity of 9 cm. per sec. = 0.2 mile per hour. An investigation by King has shown that variations of atmospheric conditions have very little effect upon the velocity determinations. With regard to the effect of pressure, this, with ordinary fluctuations is negligible, and in any case, as the hot wire anemometer measures the mass flow of a gas, i.e., the product of the velocity by the density of the gas, when this is required, no correction is necessary. Using a high temperature—say 1000° C.—King has shown that to the first order of small corrections no correction is necessary for the temperature of the gas stream.

J. T. Morris has suggested various methods of use of a hot wire as an anemometer.¹⁶ Perhaps the most suitable for general use is that contained in his Patent Specification No. 25,923 of 1913. King, it will be remembered, proposed the use of one platinum wire with large temperature coefficient of resistance, the balancing wire being of manganin with negligible temperature coefficient. Morris, on the other hand, according to the specification, proposes to make all the four wires of the bridge—a simple Wheatstone bridge is employed—of the same material, one or alternate arms of the bridge being shielded by means of a tube so that, all the resistances being adjusted to equality at any temperature, the balance is not upset with change of temperature provided there is no relative motion of the anemometer and the surrounding medium. For the purpose of calibration in Morris' experiments¹⁷ the hot wire anemometer was inserted, together with a Pitot tube, in a wind channel, and corresponding readings taken. All four wires, shielded and unshielded, are mounted in a frame and inserted *en bloc* in the stream. Using a galvanometer device in which the deflection is proportional to the square of the current, the deflection produced by the "out-of-balance" current in the bridge is very approximately proportional to the velocity of the stream. In this form the instrument becomes robust, the various parts being such as can be employed for general works' purposes. Essentially, what is required is a Wheatstone bridge as described, a cell or cells to serve as source of current, a rheostat for maintaining constancy of current in the bridge and an indication of such constancy of current, which indication may be furnished by the galvanometer employed as the indicator of the velocity of the stream, a suitable switch being arranged for the

purpose. The bridge wires, if being used for the determination of the total-mass flow of air or gas in a main, can be inserted either at the centre of the main or at any other point where the relation of actual velocity to the mean velocity in the main is known. The indicating instrument can then be calibrated directly to indicate the quantity of air or other gas flowing in the main. Used in this form, the reading of a pointer serves to indicate the rate at which gas is flowing in a pipe. The observer has no delicate adjustment to make. The only adjustment to be made is an adjustment of the bridge current to a certain specified value by means of a rheostat. This is an adjustment which can safely be left in the hands of any workman of ordinary intelligence. A skilled observer is not required. In works where rates of flow of various fluids have to be apportioned to one another the readings of one or more hot wire anemometers will enable this to be done in a rather less empirical manner than is sometimes the case at present. Moreover, the hot wire anemometer can easily be made a recording instrument, so that a record can readily be obtained of the performance of various mains so far as the passage of air or other gas through them is concerned. King¹⁸ has described a form of automatic recorder for use with his type of anemometer. The hot wire of the anemometer can be raised to any desired temperature, the readings of the indicating instrument, of course, being a function of the temperature. King in his experiments commonly used a wire at a temperature of 1000° C. For ordinary purposes such elevated temperatures are quite unnecessary. The correction necessary on account of variation of atmospheric temperature is reduced with an increase of temperature of the anemometer wire, but for general purposes, where extreme accuracy is not required, a temperature of 200° C. or so is ample. Moreover, for the determination of low velocities there is an advantage in the use of a wire at moderate rather than at an elevated temperature, in that the free convection current from the wire is thereby reduced. In any case the use of bare wires heated to anything of the order of 1000° C. is precluded in the case of gases, such as coal gas, containing combustible constituents. The possibility of ignition of the gas by the heated wire must be guarded against, and for use with combustible gases a much lower limit of temperature must be employed. Further, the author has found that using a platinum wire of 0.1 mm. diameter and fusing on to it a coating of glass, the sensitiveness of the arrangement is still such as to permit of the use of the coated wire in anemometry; in fact, the sensitiveness is very little, if at all, impaired by this treatment, if not indeed increased.¹⁹ The reason for this apparent anomaly is analogous to that advanced by Porter in the case of the effect of lagging on the radiation from steam pipes.²⁰ Porter has shown that coating a wire with glass up to about 8 cm. radius increases the radiation loss from the wire as the thickness of the coat increases up to this limit. Generally, Porter has shown that there is a critical radius of lagging equal to K/ϵ , where K is the thermal conductivity of the material of the lagging and ϵ its emissivity, such that for values of the radius less than this critical value an increase of thickness of the lagging increases the radiation loss from the heated interior. Although the greater part of the heat loss in the anemometer wire is due to convection, similar considerations hold, and the increase of surface due to the glass coating serves to increase the

effect, the wire being thin and below the limiting radius indicated by theory. This glass-coated anemometer wire is especially serviceable for use with gases easily decomposed by heat or such as are liable to contain soot or carbon from decomposed hydrocarbons. The catalytic activity of glass being in general considerably below that of platinum, such decomposition is prevented by the use of a glass-coated wire. Directions in which the hot wire anemometer can be employed are numerous. Its use where the velocity of a gas stream is required is at once obvious, and has been discussed above. Since the action of the instrument depends upon electric current, this places at our disposal all manner of recording devices actuated by the same power. Any type of recorder employed in platinum thermometry is equally applicable as a recorder with the hot wire anemometer. Relays can be actuated by the "out of balance" current to effect certain operations, thereby rendering many operations automatic. As an example may be mentioned the operation of a valve by the "out of balance" current so that the amount of naphthalene solvent injected into a coal-gas main may be proportioned to the gas flowing in the main. For the complete specification of the flow of gas in a main, as, indeed, for any vector quantity, not only must we know the amount, but also the direction, of the flow. A slight modification of the anemometer enables us to determine whether gas is flowing in one direction or the other in a main. By the use of two bare or glass-coated wires placed across the gas stream, so that one of the wires is shielded from the cooling effect of the stream by the presence of the other wire, the wire on which the stream first impinges is cooled more than the other, the "out-of-balance" current in the bridge displacing the pointer in one direction, which may be marked "up." On reversing the direction of flow of the gas stream, the pointer is displaced in the "down" direction, the shielding effect now being reversed. Owing to the extreme sensitiveness of the hot wire anemometer and its high resolving power, *i.e.*, its power to detect minute variations of gas velocities over small distances, it is a most responsive instrument in the examination of conditions of turbulent flow. King suggests the possibility of using the hot wire anemometer in order to obtain a record of the performance of a steam turbine analogous to the indicator diagram of the ordinary reciprocating engine.

As an example of the employment of the anemometer in the laboratory may be mentioned the result of an investigation suggested to the author by Dr. Charles Carpenter, *viz.*, the determination of the ratio of the volume of gas to the volume of the primary air induced in an inverted incandescent burner, and the variation of this ratio during the period when steady conditions are being established in the burner. For the purposes of experiment a Metro No. 3 inverted incandescent burner was taken. A hot wire anemometer consisting of a piece of platinum wire 0.1 mm. in diameter, glass-coated, and of about 0.6 ohm resistance, was inserted in the supply tube to the burner at some considerable distance from the heated portion of the burner and insulated from the supply tube by a plug of ebonite. The wire formed one arm of a Wheatstone bridge, the ratio arms being adjusted to 1000 : 1. The balancing resistance was 637 ohms, with a maximum variation of ± 1 ohm during an experiment. The current in the bridge was supplied by a storage battery, and was accurately adjusted throughout by means of a rheostat to 0.8 amp., the magnitude of the current being determined by a sensitive Siemens milli-ammeter

with appropriate shunt. A sensitive dead-beat Paul galvanometer was employed as indicator. The ammeter was calibrated as follows: The gas supply to the burner passed through a gas meter and sensitive balance pressure governor. The bridge was balanced when no gas was being supplied to the burner. The gas supply was then turned on and adjusted to any desired value. The steady out-of-balance deflection of the galvanometer was observed, the bridge current being adjusted to 0.8 amp. A series of observations, galvanometer deflections and hourly rates of consumption over the appropriate range of gas consumption enabled a calibration curve of the anemometer to be drawn. With regard to the determination of the volume of primary air induced by the gas, the following method was employed. The supply of primary air to the burner was drawn in through a brass tube about 6 feet long. Some little distance from the air holes of the burner the tube bifurcated, and the two limbs so formed were brazed to a cylindrical chamber

FIG. 1.

surrounding the air holes. In this manner the gas issuing from the injector of the burner received a supply of gas uniformly distributed on all sides. A hot wire anemometer was inserted in the brass tube from which it was insulated by a plug of ebonite. The calibration of the anemometer was performed in the manner described above, the air being derived from the laboratory high-pressure supply and being measured by means of a wet gas meter. All volumes were corrected to 15° C. and 30 in. pressure. The calibration curves are shown in Fig. 1. Both calibrations were made with the burner alight. The marked increase of sensitiveness of an anemometer when used in coal gas as compared with air is obvious from these curves. This increased sensitiveness arises from the very much greater thermal conductivity of the hydrogen contained in the coal gas as compared with that

of air (hydrogen = 31×10^4 c.g.s., air = 5×10^4 c.g.s.) This factor makes the hot wire anemometer—particularly the glass-coated variety—eminently suitable for use with coal gas or any gas containing hydrogen.

The anemometer having been calibrated as above, the meter connected to the air supply was removed, its place being taken by a closed vessel containing water; the air induced by the burner passed over the water, so that the anemometer was, both in calibration and in use, subject to the cooling action of air saturated with water vapour. The burner was now lit and readings of the respective galvanometer deflections taken at 3-minute intervals, the bridge current being throughout maintained at 0.8 amp. The result is shown in Fig. 2. Certain deductions from these curves are not without interest. In the case of the air and the coal gas it is seen that the consumption diminishes, reaching steady values

directly proportional to the square root of the respective densities. If we assume that the gas obeys Charles' law, we are enabled to estimate the temperature of the gas at the injector, for we have:—

$$\frac{Q_1}{Q_2} = \sqrt{\frac{273 + t_2}{273 + t_1}}$$

t_1 and t_2 being the respective temperatures at which the gas consumptions are Q_1 and Q_2 .

In the present case the galvanometer deflection obtained with the coal gas anemometer fell from 75.7 to a steady value 69.8. The respective gas consumptions are 4.36 and 4.05 cub. ft. per hr. The atmospheric temperature being $57^\circ \text{F.} = 14^\circ \text{C.}$, we see that the temperature of the gas at the injector is 60°C. In this manner it is possible to determine the temperature of the gas in its passage through the injector, and a knowledge of this temperature is of no inconsiderable value in connection with burner design. Passing now to the diminution in the primary air induced into the burner, we notice that with the burner in question the final value is not attained by a continuous decrease. There is a preliminary decrease to a lower value than the final steady value, followed by an increase to the final steady value. This effect is explained by the following considerations. Owing principally to the decrease of density of the heated coal gas, and its consequent diminished air-inducing capacity, together with the decreased consumption of gas in the heated condition, the volume of induced air decreases as the burner becomes heated. As indicated at P, the value of the galvanometer deflection throughout was slightly unsteady. This unsteadiness was a characteristic of the decreasing deflection throughout, but cannot be indicated on the remaining part of the diagram owing to the smallness of its amount. The air consumption does not fall steadily, but in a series of oscillations. It will be noticed that the air consumption falls much more rapidly than the gas consumption. The presence of the oscillations and of the final descent and subsequent ascent of the curve at P can be described as an "inertia" effect. The gas and air consumption are being reduced. At any instant of time there is a certain gas and air consumption. The burner is at a certain temperature. At the subsequent instant the gas rate is reduced. The burner, however, does not cool sufficiently rapidly to enable the air rate to attain immediately its value appropriate to the new gas rate. There is a lag in the cooling, and the air consumption is reduced by an amount greater than is appropriate to the new consumption of gas, owing to the fact that the temperature of the burner is higher than its appropriate value. This will account for the dip at P and the series of "oscillations" by which the air consumption attains its final value. From the calibration curve we find that the initial and final consumptions of air, i.e., when the burner is respectively cold and hot are 12.91 and 9.80 cub. ft. per hr. The air to gas ratio is therefore $12.91 \div 4.36 = 2.96$ when burner is cold, and $9.80 \div 4.05 = 2.42$ when burner is hot.

The well-known sharpening of the inner cone of an inverted incandescent burner as the burner becomes heated from its cold condition is therefore to be attributed to the direct effect of the pre-heating of the gaseous mixture and not to any increase in the percentage of air in the gaseous mixture, this percentage being, in fact, less in the heated than in the cold condition of the burner.

The author desires to express his gratitude to Dr. Charles Carpenter for his kind provision of every facility for carrying out the above investigation.

FIG. 2.

respectively Q and R respectively. The reason for the diminution of the gas consumption is not far to seek. Obviously the burner is cold, but it becomes heated during the course of the experiment. The pressure at the injector is throughout maintained constant, the suffix 1 referring to the gas in its cold condition, and the suffix 2 to the gas in its final heated condition, we have, V_1 and V_2 being the respective velocities of efflux from the injector and ρ_1 and ρ_2 the respective densities—

$$\frac{V_1}{V_2} = \sqrt{\frac{\rho_2}{\rho_1}} \text{ approximately.}$$

Now, the respective volumes consumed per hour measured at same temperature and pressure are in the ratio —

$$\frac{V_1}{V_2} = \sqrt{\frac{\rho_2}{\rho_1}}$$

Hence the respective gas consumptions are

DISCUSSION.

Captain C. J. GOODWIN said that years ago, before the hot wire anemometer was available, he had had occasion to measure the velocities of gases, and he had used a windmill anemometer calibrated on a rotating arm and also against a Pitot tube. These instruments had to be held more or less at the centre of the pipe that was being used, otherwise an accurate reading was not obtained. The velocity at the centre of a pipe was greater than at its periphery, and although the ratio between these velocities was known with some accuracy, and it was possible to arrive at a mean, these facts complicated the issue in the case of the hot wire anemometer. The wire occupied a good part of the diameter of the pipe, and therefore there was an average cooling effect on the wire, and the reading of the instrument would probably be different in a pipe, say, 20 in. diam. from that in a pipe 6 in. diam. Hence before such an instrument could be used for general purposes it must be calibrated for various diameters of pipes, and the use of a standard diameter pipe for each particular investigation was desirable. It did not appear possible to adapt these anemometers for use in corrosive gases—for instance, nitric oxide. The Pitot tube, on the other hand, could be made of glass. Personally, he had found the Pitot tube reasonably accurate when used in conjunction with an inclined balance level with micrometer adjustment and telescope sight; its use did not require any great skill. The author had said he did not know of any other type of anemometer which would indicate the direction in which the gas was flowing, but both the windmill anemometer and the Pitot tube did that, because if the gas flow was reversed the reading of the instrument would also be reversed. It would seem that many precautions had to be taken with the hot wire anemometer, because in the test on a gas burner the author had found it necessary to reproduce the condition of the air with which the anemometer had been calibrated, *viz.*, to have a certain definite quantity of moisture. If similar precautions were necessary in all cases when testing gas flow in a chemical works, he thought that these, as well as the cost of the instrument, would militate against its adoption.

Mr. J. W. HINCHLEY said that the Pitot tube was a most unsatisfactory instrument to use, even in conjunction with Threlfall's micrometer devices for measuring levels. Mr. Thomas' contribution to the hot wire anemometer, *viz.*, the glass coating of the wire, got rid of many of the objections which Captain Goodwin had raised. The electrical methods mentioned by Mr. Thomas were not necessarily those that would be used in a works, and it would be quite possible, by means of an anemeter and sensitive voltmeter, to measure the change of velocity across the wire by passing a constant current through the wire, and so make the instrument quite accessible for ordinary works' practice. By placing the wire right across the pipe it would be possible to determine the average velocity in the pipe. It seemed to him that the hot wire anemometer offered an advantage over the Pitot tube, although there was the possibility that eddies in the tube would be recorded with the velocity. At the same time, the hot wire anemometer might by suitable means get over the difficulties which were met with in recording the heat exchange between gases, and he hoped the author would continue his researches so that this anemometer could be made of the greatest possible use in the chemical factory by simplifying it in such a way that chemical manufacturers would not be averse to purchasing it.

Mr. G. N. HUNTLY asked as to the range within which the instrument could be calibrated.

Mr. P. J. NEATE commented on the very marked difference in the diagrams between the readings for air and the readings for coal gas, and also on the fact that the readings for moist air and the readings for dry air were appreciably different. Did not that go very much to prove that it was necessary to calibrate the instrument with the gas or air that was being measured, and that a very small change in the condition might make a very considerable difference in the reading?

Dr. H. C. GREENWOOD asked whether Mr. Thomas had extended the range of his measurements to velocities over the "critical velocity" of the gas and whether in ordinary practice he had confined his measurements to stream line motion. It was well known that at the "critical velocity," *i.e.*, the velocity at which the motion changed fairly abruptly from stream line to eddying or turbulent motion, there was a very rapid increase in the heat interchange between a gas and a metal surface. From the same point of view it would be of interest to know how much trouble was caused by the proximity of the measuring instrument to bends in the pipe. Had the author deduced any definite general law connecting the linear velocity of the gas with the heat loss from the wire, and did it follow the usual law of being proportional to about the 0.7th power of the linear velocity? Did the difference between coal gas and air which had been pointed out hold also when high velocities were used; in other words, when the motion was very definitely turbulent? In a series of experiments carried out by Messrs. Acland, Nobbs, and himself on the heat interchange in high-pressure gases, using pressures up to one ton per square inch, it was noticed that there had been practically no difference between the heat interchange resulting with gases of very different thermal conductivities. With nitrogen and hydrogen, for example, almost identical values were obtained for similar conditions as regards velocity. Another rather interesting phenomenon noticed in the same experiments was that the heat lost from a given surface under similar conditions was, over a wide range, practically independent of the pressure; the heat loss could be expressed in terms of the quantity of gas flowing through the tube per unit time without reference to the pressure.

Mr. THOMAS said that the cost of the hot wire anemometer was not such a large amount as might be anticipated from the description which he had given of it. Some little while ago his company had entered into arrangements with a scientific instrument company with regard to the manufacture of these instruments in conjunction with Prof. J. T. Morris, and the estimated cost of the hot wire anemometer after the style of that devised by Prof. Morris had really been surprisingly small. Prof. King had, moreover, suggested methods of use in which the necessary apparatus was reduced to a minimum—an anemeter, rheostat, storage cell, resistance box, and the heated wire. The windmill anemometer he had had to abandon, as in the case of a number of experiments, on calibrating such an instrument against actual velocities, he had found a difference of 50% between the indicated and the actual velocities, and that even after applying the calibration corrections supplied with the windmill. The Pitot tube in the hands of an experienced experimenter was, of course, an instrument of precision, but as used in different works and on different occasions it was questionable as to what the indications really meant. Personally he had had to abandon the Pitot tube because of the difficulties he had encountered, and Mr. Hinchley's experience seemed to have been the same.

As regarded the use of the anemometer in connection with corrosive gases, there was no reason why the whole anemometer should not be coated with glass, or with any coating material which would be suitable for the particular gas in question. He agreed that the direction of the flow of gases could be determined by the Pitot tube, but it did not give a very clear indication, *i.e.*, one visible in all cases without some adjustment being made. What he should perhaps have said was that the double hot wire anemometer was the only method which gave a clear indication that could be noticed just by a pointer. As to the limits of use referred to by Mr. Huntly, the limits as given by Prof. Morris were an inferior one of well under 1 mile per hour and a superior one of at least 40 miles per hour. Using the instrument under the conditions of calibration, there was no reason why these limits could not be materially extended. As to the use of the wire at the centre and at different points in the tube, if the motion of the gas in the tube was stream line motion, then theory indicated that at a certain point in the tube the velocity of the gas was the mean velocity in the tube, and if the anemometer was used at that point, calibration of the anemometer in a 2-inch pipe would make it suitable for use in a 6-inch or any other size of pipe in the absence of turbulence. The difficulty in connection with the use of the instrument with turbulent motion was not insuperable. Prof. King calibrated his instruments by rotating them at the end of a long arm. Prof. Morris on the other hand used a wind channel, whereas his own calibrations had been carried out by the use of gas meters. By rotating the instrument at the end of a long arm there was a tremendous amount of turbulence, and Prof. King was able to obtain the turbulent correction by putting up another wire alongside, not connected with the arm, then rotating the arm and noting the indication given by the fixed wire when the arm was rotated. In that way he was able to measure the correction due to turbulence caused by the arm. That was what he called the "swirl correction," and he had shown that it followed a definite law when the instrument was used in this manner. When used for the measurement of turbulent flow, the velocity measure was what Prof. King called the effective velocity, and experiments by Professors King and Gray had shown that in cases of turbulent flow it was possible with the use of the hot wire anemometer to obtain consistent measurements where other methods were inadequate. The heat loss referred to by Dr. Greenwood was given by an expression similar to the relation between the heat loss from the wire and the velocity of the stream. Users of the electric gas meter designed by C. C. Thomas had found that ordinary variations in the constituents of the coal gas did not materially affect the indications of the instrument. The hot wire anemometer, being likewise based on electric heating, should also yield fairly accurate values for the velocity of a gas stream for ordinary variations of the various constituents. The cooling of the wire was principally effected by convection and this was not materially affected by moderate variations of the constituents. Radiation and conduction in general played subsidiary parts in the cooling of the wire, their influence being more pronounced at low stream velocities. The water vapour in the air supply to the burner in the experiment recorded was introduced so that the anemometer was used exactly as it was calibrated. The difference in the reading caused by the absence of this precaution was less than 1% and of course for general works' use such a precaution would be quite unnecessary.

THE ABSORPTION OF ATMOSPHERIC GASES BY WATER.

BY J. H. COSTE.

II.—A DIAGRAM SHOWING THE VOLUME OF OXYGEN DISSOLVED BY WATER AT DIFFERENT TEMPERATURES AND PRESSURES, AND ADDITIONS TO THE BIBLIOGRAPHY.

In calculating the percentage saturation of water with dissolved oxygen it is usual to correct for temperature only, assuming the effect of variations of barometric pressure to be negligible, whereas they may actually affect the results by more than 2% at sea level and by greater amounts in elevated districts. To facilitate correction for both temperature and pressure I have constructed the accompanying diagram, calculated from Winkler's values (19), for *observed* barometric pressures for each 10 mm. from 710 to 780 mm. and for temperatures from 0° to 25° C. To find the volume of oxygen dissolved by a litre of water at any desired temperature and pressure, observe the point where the slanting line marked with the temperature cuts the vertical line indicating barometric pressure. The figure at the side on a level with this point indicates the volume desired, *e.g.*, pressure 730 mm., temperature 13°, volume 7.04 c.c.; pressure 776 mm., temperature 20.5°, volume 6.43 c.c. (in this case visual interpolation is easy).

A few papers may usefully be added to the list given in my previous paper (this J., 1917, 846—853). W. Black and E. B. Phelps (77) in 1911 pointed out the applicability of Fick's law of hydro-diffusion to the absorption of oxygen by still water, and showed that Adeney's "streaming" effect observed in sea water (37) was really due to the formation of a surface layer of more concentrated saline solution by blowing dry air through it. They say, "The property which was washed from the air by passing through the first tube was its dryness." The paper, which is long and very interesting,* was brought to my notice by Mr. E. Hannaford Richards, whose work on rain-water (78) has brought out the curious fact that rain-water is frequently not saturated with oxygen as at first sight might be expected. The low partial pressure of oxygen at great heights furnishes some explanation of this deficiency. C. J. J. Fox (79) redetermined by an absorptiometric method, and apparently with considerable accuracy, the solubility of oxygen and nitrogen in fresh and sea water and of carbon dioxide in sea water. He discusses the effect of the ocean in maintaining the balance of carbon dioxide in the air, a subject to which Th. Schloesing (80) called attention in 1880. T. Carlson (81) has also redetermined the solubility of atmospheric oxygen in water. His figures and Fox's are close to one another and close to but rather higher than Winkler's. A very good discussion of super-saturation of liquids with gases is given in Ostwald's "Outlines of General Chemistry" (82), in which it is shown that super-saturation must occur if pressure is reduced and gas nuclei are absent. The excess pressure of a spherical bubble appears to inhibit its formation, in theory at least. In practice the "flatness" of a sparkling liquid poured into an already wetted glass is well known, as also is the effect on such a liquid of roughened surfaces.

Vernon (83) has shown that fats dissolve appreciable quantities of oxygen. I called attention in a letter (84) appearing in this Journal to some

* I owe a copy of this paper to the kindness of Prof. E. B. Phelps.

old work on the inefficiency of layers of oil in isolating water from the atmosphere.

Rideal and Burgess (85) called attention to some aspects of the "dissolved oxygen taken up" test of the Royal Commission on Sewage Disposal.

Many analytical papers on Winkler's manganese process and on the determination of carbon dioxide have been published.

Meeting held at the Grand Hotel on Thursday, April 11th, 1918.

MR. WM. THOMSON IN THE CHAIR.

EVAPORATION IN THE CHEMICAL INDUSTRY WITH PARTICULAR REFERENCE TO THE KESTNER EVAPORATOR.

BY J. ARTHUR REAVELL.

The earliest type of evaporator is that which is direct fired. Even to-day large numbers of evaporators are merely cast iron pots, or steel vessels, which are heated directly by means of coal or coke furnaces, and in some instances are fired by gas. This type is open to many objections, in fact the laws of heat transmission show that such a type does not fulfil a single one of the conditions favourable to efficiency or economy. An instance of this is the common salt pan 60 ft. by 20 ft., with its costly flues and brickwork, requiring gangs of riveters and bricklayers for repairs, etc., to say nothing of the huge area covered relative to its capacity.

The next step was to construct evaporators consisting of a jacketed vessel, in which steam is the heating medium supplied to the jacket. This type retains most of the defects of its forerunner, and may in fact be thermally less efficient.

A later type consists of a simple tank or open pan fitted with a steam coil, for use with high-pressure steam. This makes no advance, beyond the fact that it is easy to construct. With all the foregoing types the rate of heat transmission is low, chiefly because there is very feeble circulation—even with weak liquors—falling to nothing as concentration increases. Further, there are large heat losses by radiation, often accompanied by loss of liquor by entrainment.

Vacuum evaporation.

A further development, and one of very considerable importance, was the introduction of the vacuum pan. For the first time advantage was taken of boiling under reduced pressure, and consequently at reduced temperature (see Fig. 1).

It is of interest to note that the original inventor of the vacuum pan was Howard, an Englishman.

The use of reduced pressure led, of course, to the utilisation of exhaust steam, which, previously wasted, now became of value, and gave considerable improvement in economy. The study of evaporation under artificially reduced pressure led to the development of multiple-effect evaporation.

Attempts were made to set up some form of

agitation, with a view to obtaining some motion of the liquor relative to the heating surface. This gave rise to many mechanical devices, which not only agitated the liquor, but the agitators themselves being heated, something approaching a mechanical film was created in this way. Types of evaporator were evolved, such as the Bauer or Wetzel, in which during half a revolution the liquor is in the form of a thin coating on the heating surface, yet this film has little motion relative to the heating surface. Such evaporators

VACUUM PAN.

FIG. 1.

never came into extensive use and the vacuum pan with improvements in detail held the field.

In spite of its many advantages over the more elementary types, the vacuum pan has always suffered from grave disadvantages in practice. Attempts, most of them unsuccessful, though showing a vast amount of ingenuity, have been continuously made to evolve a type of evaporator which would retain the improvements manifest in the pan, but which would be free from the drawbacks which are inherent in this type.

MODERN VACUUM EVAPORATOR.

FIG. 2.

To obtain even moderate circulation and consequent heat transfer, a calandria type is almost essential, and having short tubes the number is great, consequently troubles with faulty expansion and leakage are multiplied. Moreover, large diameters lead to structural difficulties which prevent the use of high pressure or even of what are to-day considered medium pressures. Further, the liquor to be concentrated is present in large bulk, and as a result of this, and of feeble circu-

lation, the ebullition of steam frequently occurs irregularly in the lower portions of the mass, resulting in sudden entrainment or "blowing over."

Secondly, since the rate of evaporation is not constant, but is rapid in the first stages and falls off as concentration proceeds, there must be a compromise when designing the dome and vapour outlet. As a result, if at first the speed of the vapour is too great, continuous entrainment takes place in the form of drops and vesicles.

Again, by evaporating in bulk, every particle of solid in solution is subjected to prolonged heating or "stewing." For this reason expensive vacuum plant is often attached to the pan, simply to keep down the temperature.

There is no economy in the use of a vacuum unless by this means exhaust steam, otherwise wasted, can be made available for heating purposes. As will be shown later, it is better to use, in many cases, an evaporator designed on more correct principles, to employ boiler steam, and to work in single or multiple effect under pressure.

Added to the foregoing, lack of circulation brings in its train quick incrustation.

The film evaporator.

As the laws of heat were investigated, especially those of heat transfer between liquids and solids, the importance of the movement of the liquid itself relative to the heating surface was more clearly realised.

In 1830, Dubrunfaut set down his idea of an ideal evaporator in as far as sugar liquors were concerned as follows:—"Concentrate the juice as rapidly as possible so as to avoid any alteration; give the liquor to be evaporated great speed.

FIG. 3.

and, if possible, accelerate the movement of the liquor so as to evaporate in the form of a thin film." What this authority conceived in 1830 as a theoretical ideal, Paul Kestner has to-day accomplished as an actual fact. The "film idea" has been embodied in different types of apparatus, including the following:—Lillie, Yaryan, Schwager, Claassen, Greiner, Kestner.

The Lillie pan, arranged with horizontal tubes, is shown in section in Fig. 3. The feature of this evaporator is that the liquor is delivered by means of a pump to the top of the nest of horizontal tubes, and is distributed over the outer surface, falling alternately in film and drops into the base of the evaporator again. The heating steam is carried through the tubes, which are slightly

tilted to one end, so that all the condensed water is drained. The disadvantage of this design is that the film is in no way perfect, because the liquor is formed in large drops on the under surfaces of the tubes, and thus part of the surface is not as effective as the remainder, whilst the same defect occurs, inside the tubes, in the case of the condensed water, greatly reducing the transmission efficiency of this portion of the surface.

The Yaryan (Fig. 4) is also a horizontal type evaporator, but differs from the Lillie in that the liquor to be evaporated is inside the tubes, and

FIG. 4.

the heating steam outside. This has a great many advantages, but the difficulty of feeding a large number of tubes in a horizontal position so that all equally and regularly obtain the same amount of liquor, is obviously great, while the water condensing on the outer surface of the tubes drops from one tube to another, so that the tubes of the lower range are waterlogged and not as effective as those of the upper range.

The Schwager, Claassen, and Greiner evaporators are more or less variations of the same principle, and are not of special interest.

Kestner evaporator.—Mr. Paul Kestner, in the course of a large experience in all types of evaporators, had particularly studied the horizontal film evaporator, and found out its great limitations. He therefore set himself to discover, if possible, a means of producing a perfect film, and the principle upon which he founded his design is shown in Fig. 5 herewith.

The tubes are 23 ft. long. The liquor is fed into the tubes from a tank about 3 ft. above the bottom tube-plate, and assuming that this liquor is hot, then on steam being applied to the outer surface of the tubes, ebullition at once commences inside, releasing a large volume of steam which must find its way to a region of lower pressure by passing up the tubes. As a result we have the phenomenon of the climbing film. The liquor and vapour on leaving the top of the tubes meet a fixed centrifugal ball, where the liquor is separated from the vapour, the liquor passing to the concentrated liquor tank, and the vapour to the atmosphere or to the condenser. The velocity of the liquor itself is thus used by means of centrifugal action to separate the vapour from the liquid.

Heat transfer under actual working conditions.

In endeavouring to evaporate a liquid, one of the great objects is to transfer the maximum number of heat units per unit area from the heating medium to the liquor to be evaporated.

Based on deductions from actual apparatus, and bearing in mind the results of theoretical and experimental research, the quantity of liquid evaporated in a tubular apparatus heated by steam would appear to vary with the following

factors:—(1) Area of heating surface. (2) Temperature drop or "temperature head." (3)

Velocity of the liquid relative to the heating surface. (4) Velocity of the heating steam. (5) Specific volume of the heating steam. (6) Viscosity of the liquid.

In practice, of course, the transfer is very far from being the heat conductivity obtained through the ideal cubic centimetre of pure metal. The conditions under which heat is supplied in actual practice to the metal are very different from those in laboratory experiments, whilst the transfer takes place through a combined wall of water, oxide, metal, and incrustation.

The table of conductivity shows the relative values of the different metals.

The next factor is heat drop. Consider a coil pan; the transmission of the heat depends—other things being equal—upon the heat drop, or temperature difference, that is to say, if the steam in the heating coil is at 10 lb. pressure, the temperature of the steam is 115.5° C. Assuming water in the vessel, the boiling point of the water is 100° C., then there is a drop, or temperature head, of 15.5° C.

When vacuum is applied, the object is to increase this temperature drop, and, taking the same figure as above, and with a closed instead of an open pan, by the application of 24 in. vacuum, the temperature of the steam evolved from the liquor would be 60° C. instead of 100° C., so that the temperature drop is increased from 15.5° to 55.5° C.

TABLE I.
RELATIVE HEAT CONDUCTIVITY.

Grm. Cals. per cm. ² , per cm. thick, per 1° C. drop per second		Comparative figures, Copper = 1000
Copper	1.041	1000.0
Iron	0.167	160.0

Silica	1.75	0.87
Water	0.98	0.49
Air	0.010	0.020

Now, as the rate of evaporation varies directly as the difference in temperature, a material advantage is gained by this increased temperature head. However, while the rate of evaporation is proportional to the difference in temperature, there may be other factors which militate against this. That other factors do occur is evident, because by increasing the steam pressure the evaporation does not always increase proportionately.

It should be borne in mind, also, that temperature drop has not the same value in any part of the scale. It is of more value higher up in the scale; for one reason the steam is denser, and, therefore, more heat units come in contact with a given unit of area in a unit of time; but in the case of a pan or jacketed tank the designer cannot take full advantage of operating in the higher ranges or with largely increased drops, because constructional difficulties arise in the case of large flat surfaces and to a lesser degree with large diameters, and also because the heating surface is not swept free of the steam bubbles generated.

In a "film" type evaporator high temperatures can be used with advantage, because the surface is so disposed that the diameter is very small, even for great surface areas, whereas, in a bulk evaporator, such as a vacuum pan, a large surface area of tubes means large diameter. Moreover, if high temperature and, consequently, high pressure is employed in this type of pan, many liquors which are sensitive to heat are decomposed, because they are too long in contact with the heating surface. On the other hand, in the "film" type evaporator, which works continuously, the liquor is in contact with the heat for a few seconds only and no "stewing action" takes place.

Heat transfer also depends upon (a) the velocity of the liquor and vapour in relation to the heating surface, and (b) the velocity of the steam in relation to the heating surface.

Speaking broadly, it may be said that the heat transmission varies directly as the square root of the velocity, so that if either velocity is quadrupled, the coefficient of heat transmission is doubled. This is commonly spoken of as the effect of "circulation."

In a tank with heating coils or jacketed tank, there is a large body of liquid which is a considerable distance away from the source of heat, and unless mechanical circulation is adopted, the rate of transmission of the heat to the various parts of the liquor is very low.

In an ordinary type calandria pan the circulation is not as positive nor as certain as in a continuously operating pan. Further, with a large number of short tubes the cross-sectional area of the tubes is large in relation to the heating surface, consequently when movement does take place the velocity is low.

In a vertical climbing film evaporator, the number of tubes is small, the length is great, and there is positive circulation at high velocity, 30 to 60 metres per second; hence the heat transmission is very high, and the time contact exceedingly short—momentary in fact.

Then, again, in a pan the area of the space occupied by the heating steam is large, and the velocity is consequently low; as a result, there is difficulty in evacuating the air and non-condensable gases, whilst the condensed water is not swept from the heating surface.

In a Kestner "film" evaporator the area of the steam space is small, the speed of the steam is high, and the gases are collected definitely in a small space, so that they can be easily removed. It is also found—and this is of the greatest impor-

tance—in regard to high velocity, that the speed of the liquor tends to reduce scaling to a minimum, and has a scouring effect, *e.g.*, a Kestner evaporator remains clean throughout a sugar campaign of many weeks, whereas a pan is cleaned every Sunday. High velocity is also very important in regard to the physical properties of the liquor, in that it gives a short-time contact.

To obtain high velocity, it is necessary to arrange the heating surface so that the ratio of the area of the heating surface to the cross-section of the tubes is as great as commercial construction and theoretical considerations will allow. Fortunately in this case practice can be adapted to theory, and in the climbing film evaporator the tubes are 7 metres long and 50 mm. in diameter, a ratio which has been found most successful in actual use. Other factors, such as the friction of the vapours, come into force and nullify the advantages of using longer and narrower tubes.

Another great advantage obtained, due to this very high liquor velocity in the "climbing film" tube, is that it makes possible a perfect separation of liquid and vapour. The vapour and liquor leave the tubes at about 30 metres per second and enter a separator at this high speed. They are caused to change their direction at right angles, without shock, and by utilising centrifugal force in this way, the heavier particles of the liquor are thrown out, due to centrifugal action, against the side of the separator, allowing the vapour to rise and pass away freed from the liquor.

Entrainment.

The prevention of entrainment, known colloquially as "frothing" or "blowing over," is of the utmost importance in evaporation. In the ordinary open tank, wherever the boiling is rapid, a considerable amount of liquid is carried away because the small particles, always projected vertically from the surface of a boiling liquid, do not fall back into the mass but are swept away by air currents. In the ordinary vacuum pan, entrainment trouble, that is, the carrying away of the product with the vapours, is a very common difficulty for the reasons previously stated.

In any properly designed continuous evaporator, the amount of vapour leaving the apparatus is constant. It is, therefore, easy to determine by definite calculation the size of separator required to deal with the vapour, so that a definite speed is attained and no entrainment takes place.

Multiple effect.

The principle of multiple effect evaporation is that by alternate evaporation and condensation the latent heat is exchanged successively, as a means of separating water from solids. Thus—neglecting losses and self-evaporation, etc.—if 1 kilo. of steam be condensed in the first calandria of a triple effect through which liquor is passing, 1 kilo. of condensed water would be produced from the liquor in each of the calandrias of Nos. 2 and 3, and 1 kilo. of vapour would be produced in No. 3. If, therefore, an operation commences with 1 kilo. of boiler steam and 3 kilos. of water to be evaporated, then 3 kilos. of condensed water is recovered and 1 kilo. of steam at a lower temperature and pressure than that of the live steam supplied to the first effect. The cycle of operations finishes by producing 3 kilos. of condensed water and 1 kilo. of vapour at a low temperature and pressure—thus showing that what has happened is merely a transfer of heat.

According to theory, in designing a multiple-effect evaporator, when an equal drop is required in each effect, the different effects should have a different amount of heating surface, and although this has been very often carried out, it has been

definitely found in practice that the best average results are obtained, both from the point of view of first cost and operating expense, by adopting the same heating surface in each effect.

TRIPLE-EFFECT EVAPORATOR.

FIG. 6.

The object of multiple-effect evaporation is simply to reduce the cost of removing the water. The following table shows the economy obtained by means of multiple-effect evaporation.

TABLE II.
COMMERCIAL FIGURES FOR WATER EVAPORATED
PER 100 UNITS OF STEAM.

Steam 100	Single	Doub'e	Triple	Quadruple
Water	95	150	220	300

COMMERCIAL FIGURES FOR WATER EVAPORATED
PER 100 UNITS OF COAL.
COAL AT 6:1.

Coal 100	Single	Double	Triple	Quadruple
Water	570	900	1320	1800

Example—1000 kgs. of water evaporated in triple effect.

$$(a) \text{ Steam required} = \frac{1000 \times 160}{220} = 450 \text{ kgs.}$$

$$(b) \text{ Coal required} = \frac{450}{6} = 76 \text{ kgs.}$$

Actual working figures taken from a Kestner triple-effect evaporator concentrating tan extract liquors show that 23 tons of water was evaporated per ton of live steam in the first effect, so that, based on coal at 7:1 in the boiler, 16½ tons of water is evaporated per ton of coal.

In multiple-effect evaporation assume that the temperature of the heating steam in the first effect at 6 lb. per sq. inch is 110° C., and that the vacuum is 26½"=50° C. in the condenser, then the total available temperature head or drop is 60° C. If this is to be spread over the three units of a triple effect, the average drop on each effect is 20° C.

Now the point that arises with any evaporator is, what is the minimum average drop which can be used for each effect, as this obviously fixes the number of effects—and consequently the economy to be obtained—between any fixed temperature limits?

If economy is of the utmost importance, because of high price of coal, or for other reasons, and where capital cost is of less importance than economical working, with the climbing film it is possible to operate with a greater number of effects between given temperature limits than with any other type of evaporator.

The extremely small drop required by a Kestner climbing film evaporator is illustrated by the

following. According to Messrs. Bell Bros.' patent for the generation of power from slag, molten slag is poured into a vessel, and generates steam at atmospheric pressure. The idea was to carry this vapour direct into turbines of the low-pressure type, working at, say, 28½" vacuum. It was found, however, that the steam contained chemicals of different kinds which attacked the rotor of the turbines. A Kestner climbing film evaporator was therefore installed which would provide clean steam and which would operate efficiently with a minimum loss of temperature drop. The evaporator operated on a heat drop of 5° C. and gave a heat efficiency of 91%, based on average working conditions.

Use of saturated steam, etc.

The idea that superheated steam can be advantageously used for evaporation is fallacious, because to evaporate quickly the heating steam must condense rapidly. Now, superheated steam acts like a non-condensable gas, and until it is cooled down to the temperature corresponding to its saturation pressure, practically no evaporation takes place. According to M. Normand, the rate of condensation with superheated steam is 20 to 30 times slower than with saturated steam.

There is also quite an erroneous idea of the value of waste gases for evaporation purposes. At first sight the use of waste gases holds out many apparent advantages, but after many years' study of the problem this idea has been dropped except in special circumstances. In the first place, owing to the enormous difference in the number of available heat units per lb. of steam, compared with those available in a pound of hot gas, the volume of gas passing over the outer surface of the evaporating tubes must be very large, and this, consequently, calls for very large calandrias with large spaces between the evaporating tubes. One pound of steam will give about 1000 available heat units, whereas, even assuming 1000° C. temperature drop for the gas, and a specific heat of 0.25, the heat units available per lb. of gas are only about 250.

In addition to this difficulty it must be remembered that the heat transmission between saturated steam and metallic tubular heating surfaces is very much better than the transmission between hot gas and similar surfaces. As a consequence, in order to effect the same evaporation per hour, it is necessary to provide from four to seven times as much area of heating surface when using hot gas as when using steam.

Further, when evaporating to predetermined density, it is very necessary that the temperature of the heating medium should be easily controlled and easily kept constant, two factors which are readily obtained with steam, whilst they are not nearly so readily obtained with hot gases.

High concentration.

The advantage of a continuous evaporator of the "film" type in regard to high concentration is very great. In this type of evaporator it is possible to concentrate liquors up to very high densities, in some cases to commercial dryness. For instance, in the climbing film evaporator, wood extracts can be concentrated under atmospheric pressure, from, say, 30° B., up to 85% solids. Owing to its temperature, the finished product is liquid, and runs by gravity out of the evaporator. On cooling the extract solidifies.

Any caustic soda liquors, excepting those prepared by the Leblanc process, can be concentrated up to 60% Na₂O, or 76% NaOH, direct in a Kestner evaporator; this is, in a great many instances, quite sufficient for commercial purposes. This method is much more economical for producing solid caustic than the use of a direct-fired

pot. Moreover, it can be carried on continuously in series with a multiple-effect evaporator.

Owing to high solubility, some inorganic liquors, such as ammonium nitrate solutions, can be concentrated up to a very high density in a Kestner film evaporator, without the use of vacuum, and without precipitation of crystals, to as high as 85% solids. As the liquor is evaporated under atmospheric pressure, it leaves the evaporator at about 136° C., runs into a crystalliser, and yields crystals very quickly. Such high densities mean that a maximum amount of crystals is obtained for a given weight of mother liquor.

The above are merely instances to show the advantages obtained by high concentration in this type of apparatus.

There are other types of Kestner film evaporators which have been evolved from the ordinary climbing film, and one, of particular interest at the present time, which has been in very large demand, is that known as the "Salting" type evaporator (see Fig. 7). This apparatus consists of a central separator, around which are arranged calandrias, in which the actual evaporation takes place. There is a circulation of the liquor from the separator into the calandrias, and from the calandrias back into the separator. In the separator crystals are thrown down as illustrated in Fig. 7.

This salting type evaporator is of great value when dealing with liquors containing two salts, one of which, owing to its lower solubility, can be precipitated, whilst the more soluble remains in solution. A typical example of such a liquor is that produced in a potash recovery process. This liquor contains chiefly potassium nitrate and sodium chloride; the solubility of the latter increases very slightly with the temperature and then remains almost constant, whilst the solubility of the potassium nitrate increases rapidly with the temperature. When both salts are present in solution a critical temperature is reached at which practically the whole of the sodium chloride is thrown down, whilst the whole of the potassium nitrate remains in solution.

Such liquids are usually concentrated in a double-effect evaporator. In the first effect in which the temperature is highest, concentration is maintained at such a point that the less soluble salt will not remain in solution but falls down into the bottom cone of the separator in the form of crystals. The liquor from this effect may be either drained out from a salt box and then carried over to a second effect, or in some cases may be

carried over directly from the first effect separator. In the second effect further concentration of the more soluble salt is carried out by means of the vapours driven off from the first effect.

Such problems involving a dual solution must of necessity be carefully examined and dealt with on their merits.

In some cases the more soluble salt is evaporated to crystallising point in the second effect, in others the concentration is only carried to such a point that the liquor may conveniently be taken as a highly concentrated solution to a rotary crystalliser, and thence to a centrifugal machine, from which the mother liquor is returned to the system. Such a method is adopted when the solubility of the second salt is extraordinarily high, such, for example, as ammonium nitrate, or when impurities are present. In the latter case, when the mother liquor becomes sufficiently charged with impurities, it is not returned to the system but treated separately.

DISCUSSION.

Mr. F. H. TERLESKI inquired the reason for washing out evaporators of the salting type every 12 hours. Another point was with regard to breakdowns. It might be necessary to put in an evaporator tube, 23 feet long, under a roof supporting a tank. In order to replace that tube the whole calandria would have to be taken down, whereas this would not be the case with an evaporator having shorter tubes. A further question was the number of long tubes in the Kestner evaporator and the possibility of clogging, which was not so serious in the case of the short-tube pan evaporator. The present salting type of evaporator was a distinct improvement upon the early types. With the ordinary multiple-effect pan evaporator where crystals were deposited it was not necessary to remove liquids to tanks outside to crystallise, with resulting heat losses. Crystallisation was continuous, drying was continuous, or practically so, and evaporation proceeded while the crystals were drying; this was not the case in the salting type illustrated. Taking out large volumes of liquid to deposit crystals and sucking back the cold mother liquor with less concentrated solutions would account for a fair amount of heat loss. The velocity of the climbing film was dependent upon the high speed of the vapours. Where entrainment troubles had to be considered there must be complete separation in relatively large volume areas in order to allow the liquid and the vapour to separate. The velocities in the Kestner evaporator were very considerable, and as the liquid and vapour separated at right angles without shock the separation was possibly complete. When, however, there were large quantities of liquid and vapour travelling at high velocities the possibilities of complete separation were greater where the vapour was in the out-take pipe of an ordinary evaporator, and where there was a distance of five or six feet to the header pipe from the calandria the losses should be less, when there was practically only vapour with a minute amount of liquid, as compared with an evaporator in which there was a separation of liquid and vapour practically at the same level, as set out in the Kestner type.

Mr. J. R. HANNAY said that from 80 to 90% of the steam generated in a calico-printing works was used for the evaporation of water from the goods which were running through the works. Anything that would tend to increase the efficiency of the drying plants would go a long way towards reducing coal consumption. Mr. Reavell had referred to the fallacy of the use of superheated steam for evaporation purposes. In the calico-printing trade there had grown up of recent years a very large practice of taking low-pressure

steam back to superheaters in the boiler house and then passing it through the drying cans. An experiment recently made in the works with which he was connected gave very disappointing results, and the opinion had been expressed that the superheaters were not working properly because the use of superheated steam had not resulted in much increased drying power. The problem of drying cloth over cylinders was one which required the attention of heating engineers.

Mr. NAGEL said that in one of the works with which he was connected two of the largest Kestner evaporators in existence had been installed and were giving excellent results.

Mr. THOMAS TAYLOR asked whether, owing to the great speed at which the film climbed, it would be possible to evaporate a liquor, which in the ordinary way would affect the metal of the tube, but might not do so owing to it being in contact for such a short time.

Dr. A. C. DUNNINGHAM inquired whether the Kestner film evaporator had been applied to the evaporation of brine in the manufacture of ordinary salt. He was impressed with the statement that the rapid film prevented the silting up of the tubes. How frequently was it necessary to wash out the tubes, because a statement had been made at one point in the paper that it was only necessary to do so at an interval of something like three weeks in certain cases?

Mr. BOOTH thought there might be a considerable loss of heat in lifting the liquid from a low level up to a comparatively high distance and also owing to the friction against a narrow tube to the high level of three metres.

Mr. REAVELL stated in reply that in the salting type evaporator there was not the same high efficiency of heat transmission as in the case of the film evaporator, dealing with liquors containing no salt in suspension, but even so, the Kestner evaporator maintained its advantages proportionally over the ordinary pan system. In the case of a liquor containing no solids in suspension, and being evaporated in an ordinary climbing film evaporator, there was an advantage of perhaps 50% in the heat transmission, as against the salting liquor in a salting type evaporator. He had not intended to convey the impression that in the case of the salting type evaporator every liquor must be taken out of the evaporator for crystallising purposes. The exact opposite was the case, but there were some instances in which impurities came down first, or where a special size of crystal was required, in which the liquor was evaporated to a very high density in the salting type evaporator, and then crystallised in an outside crystalliser. In a large majority of cases the salt crystals were precipitated directly in the separator of the Kestner salting type evaporator, this separator being quite independent of the evaporating tubes, whereas in a pan, any solids precipitated remained in the same vessel as the evaporating tubes themselves. The crystals were withdrawn from a Kestner salting type evaporator periodically by means of a salt box. By arranging a number of calandrias around a central separator, it was possible to have one calandria free for cleaning and repairing purposes, whilst the others remained continuously at work, whereas in the case of a pan a few leaky tubes meant the closing down of the whole evaporator. The Kestner climbing film evaporator had never been adopted by Mr. Kestner for liquors precipitating crystals. With regard to entrainment, in a pan, the provision of large volumes in the dome would not prevent the continuance of "frothing" once it had begun, but the whole mass of liquor would tend to be lifted as a "frothy" mass into the dome of the pan, and

then carried over to the condenser. The Kestner evaporator, on the contrary, contained a relatively small quantity of liquor at any given moment, and this moving at high velocity was thoroughly separated by means of the centrifugal baffle. It was unlikely that the Kestner evaporator would be put under a roof supporting a tank, especially as, owing to the extraordinarily small amount of floor space occupied by a Kestner evaporator, there was great latitude with regard to position. Concerning the treatment of acid liquors, experience had shown that owing to the high velocity in a Kestner evaporator certain liquors could be dealt with which could not be concentrated in any other apparatus. With regard to the loss of heat in raising the liquor from the low level to the high level of the climbing film evaporator, the work done when expressed in thermal units was relatively small, and the apparatus being lagged, a certain amount of it was recovered again as heat in the centrifugal baffle, and as velocity energy when the liquor passed from one effect to a second.

Nottingham Section.

Meeting held at Nottingham on April 24th, 1918.

DR. R. M. CAVEN IN THE CHAIR.

DISCUSSION ON BLEACHING AND DYEING UNDER WAR CONDITIONS.

Mr. S. J. PENTECOST, in opening the discussion, mentioned that the bleaching trade had suffered considerably through the withdrawal by the Government of sulphuric acid, which was looked upon as essential in the treatment of cotton goods. This withdrawal had necessitated the use of nitre cake, which had several drawbacks; one of the most serious was that nitre cake always contained iron which resulted in the production of a faint yellow colour if the bath should become neutral, and this was possible, especially in the case of the continuous process for bleaching. In this method the goods to be treated were introduced wet and the strength of the bath was maintained by the addition of a solution stronger than the solution in the bath. Owing to the variations in the degree of acidity of the nitre cake it was possible for the bath to become neutral, especially if a previous bath had been alkaline. In a paper dealing with oil stains on lace (this J., 1897, 409), he had emphasised the fact that these stains tendered the cotton owing to the presence of metal from the bearings, etc., and that the strength of the cotton was reduced as the result of catalytic action being set up in the bleaching solution. Iron deposited in the cotton by nitre cake caused a similar trouble.

A difficulty which was likely to become more acute in the future was due to the increasing scarcity of soap.

A further difficulty had arisen owing to the scarcity of bleaching powder; this had caused bleachers to consider the process of electrolysis salt solutions, and firms were at present prepared to supply plant for this purpose. One firm accomplished the object by electrolysis a salt solution of 26° Tw. (sp. gr. 1.13) with a current of 85 amps. at 110 volts, whereas another emphasised the necessity for employing a low voltage and used 600 amps. at 30 volts. The latter process gave a solution containing 9–10 grms. per litre, whereas the former yielded up to 15 grms. per litre. The makers of the electrical apparatus stated that the electrical process was as cheap as the bleaching powder method. The speaker, however, had not been able to confirm this and the results of

trials had shown that the electrolytic method was slightly dearer. However it had the advantage of cleanliness, and in the matter of the strength of the resulting fibre there was very little to choose between the methods.

In connection with dyeing the chief difficulty had arisen owing to the shortage of colours. However since 1916 British firms had made wonderful progress and were now in a position to supply most of the present needs. Two local firms had put down extensive plant for the production of oxidation Aniline Black, a dye which possessed exceptional qualities as regards fastness to light and beauty of shade. It was formerly produced on cotton hosiery very cheaply by the Germans, and was known as "Hermsdorf" Black.

Dr. E. P. HEDLEY mentioned that in America all the cotton was bleached electrically. He attributed the failure of the process in England to the freight charges on the salt, the cost of which was 15s. per ton in Cheshire and 27s. per ton in Northern Scotland and the South of England. As a source of power in some districts coal was as economical as water in England, owing to our coal deposits. Bleaching powder was objectionable in use owing to its bad effect on the machinery and the workpeople. Further it was not readily soluble and was drawn away on the fibre. There were three possible ways of obtaining bleaching solutions: (a) from bleaching powder; (b) by passing chlorine into sodium carbonate solution; (c) by the electrolysis of salt solution. The first method, besides the disadvantages above referred to, had this disadvantage that if sulphuric acid was used as the souring agent calcium sulphate was precipitated on the fibre and owing to the formation of an oxycellulose there was a weakening of the fibre. This drawback could be overcome by employing hydrochloric acid, which would form calcium chloride and this could be subsequently removed by washing. In the electrical method the compound formed was the sodium salt of hypochlorous acid, and even if sulphuric acid were employed the formation of sodium sulphate was not harmful and did not bring about the "tendering" of the fibre. Also the ash in the case of materials bleached with bleaching powder was considerably higher than that obtained when sodium hypochlorite was employed—1.2–1.5% in the former case and 0.03–0.08% in the latter. As liquid chlorine was now readily obtainable the process of making hypochlorous acid by the action of chlorine on sodium carbonate might be seriously considered by bleachers, and the reaction might be carried on by passing the chlorine beneath a bell-shaped cover immersed in the solution and provided with a stirrer. A suitable plant designed by the speaker was working efficiently.

Mr. J. H. DUNFORD mentioned in connection with the scarcity of sulphuric acid, that at present the Government were releasing sulphuric acid for the purpose of making soluble phosphates.

Mr. J. M. WILKIE asked if there was any marked effect in the products from the different methods of bleaching attributable to the small differences in the ash content.

Mr. PENTECOST replied that in many cases a high percentage of ash was a decided advantage from the seller's point of view and that it was only in the case of cotton cellulose which was to be used in the manufacture of explosives that a low ash content was essential. The bleaching powder process was now firmly established, and so far the results of the electrolytic method had not been exceptionally good. The electrolysis of the salt solution was carried out in slate vats and the cheapest source of power locally was a gas engine coupled to a generator.

MR. L. P. WILSON IN THE CHAIR.

UTILISATION OF WASTE NESSLER SOLUTION.

BY WILLIAM CLIFFORD, ASSOC. M. INST. C.E.

In view of the scarcity of iodides, it is important to recover and utilise the mercuric iodide from the solutions remaining after determination of ammonia by means of Nessler's solution. Usually these liquids are thrown away.

A simple method for treating these residues is to pour them into a "Winchester" quart bottle and add a few c.c. of sulphuric acid; mercuric iodide is precipitated, and the supernatant liquid is thrown away. When sufficient iodide has accumulated it is dried and kept for use.

After various attempts to decompose the mercuric iodide, with a view to obtaining sodium iodide, the decomposition was effected by means of iron filings. Metallic mercury and ferrous iodide are obtained, and the latter is treated with sodium carbonate or caustic soda, which precipitates the iron and yields sodium iodide. 200 grms. of mercuric iodide is mixed with 20 grms. of iron turnings in a litre flask and 500 c.c. of distilled water added. The flask is left on the water oven or water bath. The reaction proceeds at once and is completed in about an hour. The green solution is filtered and boiled or allowed to stand overnight on the water bath, when the colour changes to a ruby red. The iron is then precipitated with an alkali carbonate or hydroxide. A second precipitation is needed to bring down the whole of the iron. The filtrate from the second precipitation may be used without further treatment for oxygen absorption determinations. 85% to 90% of the mercury is recovered in the metallic state.

It may not be generally known that sodium iodide and caustic soda may be used in place of potassium iodide and caustic potash in making up Nessler solution.

DISCUSSION.

The CHAIRMAN said that a solution of alkali hydroxide and glucose was fairly effective in reducing metallic salts; it would probably give a soluble iodide at once and at the same time precipitate metallic mercury.

MR. HEAVEN enquired whether the final product was fairly satisfactory, or whether it required treatment to decompose the iodate. In trying recently to recover copper iodide precipitates he found that the residue required considerable working up before it was possible to get a reasonably pure iodide.

MR. CLIFFORD, in reply, said he had not tried glucose. No difficulty had been experienced with regard to the utilisation of the iodide, as it was in a fairly pure condition. About 85% of the mercury was recovered as metallic mercury by grinding up the dried residue in a mortar. The whole of the mercury was not removed by this method, minute globules remaining adherent to the iron.

DR. R. S. MORRELL IN THE CHAIR.

DISCOLORATION OF WHITE PAINT.

BY D. F. TWISS, D.SC., F.I.C.

In the use of a white "enamel" of good quality trouble was experienced in the tendency of the dried films to undergo discoloration, especially when articles painted with it were stored in a fairly warm situation; under these conditions the whiteness was soon replaced by a yellow or yellowish brown colour, the result being much the same whether the painted surface was exposed to the light of an ordinary room or was kept in the dark. The enamel or paint normally consisted of an oil varnish mixed with zinc oxide as pigment, and at first the almost natural tendency was to attribute the discoloration to the presence of some impurity in the pigment; as zinc oxide pigment at the present time is also often adulterated with lithopone, consisting mainly of zinc sulphide and barium sulphate, the zinc sulphide in this, by slowly reacting with lead compounds simultaneously present in the pigment or in the oil, might give rise to a gradual discoloration. Although these impurities were found in some samples of the paint, not only did exposure of dried films in an atmosphere of hydrogen sulphide fail to induce a greatly accelerated colour change, but samples of similar paint were discovered to be free from lithopone and lead and yet to undergo discoloration in a similar manner. A peculiarity of the discoloration was that it appeared to be confined mainly to the outer surface of the films, the under side against the painted article being affected to a relatively slight extent.

It is an interesting fact that some zinc pigments are not above suspicion as to their fastness; lithopone on exposure to light undergoes a reversible colour change, which, however, is hindered by admixture with linseed oil, an extreme and probably exaggerated statement of such behaviour having been made many years ago in a description of the behaviour of a lithopone paint on certain gate posts, which were "black all day and white all night" (Chemical News, 1881, 43, 283). Zinc oxide, however, is relatively insensitive to light, and the fact that light was not essential to the discoloration now in question disposed of the possibility that the trouble was due to the effect of light either on zinc oxide or on any accompanying lithopone.

Another common cause of the discoloration of white paints, which is often not fully realised, is the ease with which the surface becomes stained with dirt from the external atmosphere, and, amongst others, H. E. Armstrong and C. A. Klein (this J., 1913, 329) have drawn attention to the fact that the blackening of white lead paints is frequently due to this cause rather than to the action of atmospheric hydrogen sulphide. In any case the conditions under which the present discoloration occurred rendered this explanation inapplicable.

As the evidence indicated that the source of the discoloration was not in the pigment, attention was turned to the medium, and the seat of the trouble was then located. When a little of the medium was separated from the mixture and was absorbed into paper free from mineral impurities, the dried film, on being kept in a warm place, was found to develop gradually a

marked yellowish brown colour, a very marked change occurring in a few hours at 60° C. Linseed oil free from "gum," either alone or mixed with pigments, was found to suffer a similar alteration to the oil varnish, but in a still more marked degree.

In order to investigate the change further, strips of paper coated with the white paint, and also with linseed oil only, were hermetically enclosed in glass tubes from which the air had been expelled by a current of carbon dioxide; this gas was generated from marble and recently boiled dilute hydrochloric acid, and was then washed with water and dried with sulphuric acid before use. It was expected that under these conditions the discoloration would be prevented, but the unforeseen result was that the development of the yellow or brown colour occurred even more readily. As this colour change was effected in the dried paint film in a few hours at 60° C., in an atmosphere of carbon dioxide, the alteration in the oil would appear to be independent, not only of the oxidation to linoxyn, but also of the polymerisation process for which a temperature in the neighbourhood of 260°–280° C. is necessary (e.g. see Morrell, this J., 1915, 105).

Tests were made as to the conditions under which the yellow or brown discoloration could be removed and the original whiteness restored. It is a matter of common knowledge that such bleaching may generally be effected by exposure to sunlight, but for convenience a Cooper-Hewitt mercury vapour lamp was used as a more readily available source of chemically active radiation. In accordance with the natural expectation, it was found that, unlike the discoloration process, the bleaching process required the presence of air or oxygen. When the discoloured film, sealed in a glass tube containing carbon dioxide, was exposed to the actinic rays of the mercury lamp the discoloration persisted, although it changed somewhat in tint, becoming a shade browner. Bleached films could again be discoloured by keeping in a warm place, and the discoloration and bleaching processes could be repeated many times in succession, the tendency to discoloration then appearing to undergo gradual but only slight diminution. It was not possible to prevent the subsequent occurrence of discoloration in a dried white film by a preliminary prolonged exposure to ultra-violet light with access of air.

During the course of this work the following brief reference to white paints was noted in Lewkowitsch's treatise on "Oils, Fats, and Waxes" (Vol. 3, p. 61):—"The paint oil *par excellence* is linseed oil. In the manufacture of high-class white paints for the use of artists cold pressed walnut oil and poppy seed oil are employed in considerable quantities" (see also *ibid.*, Vol. 2, pp. 100 and 125). Although this statement is not definite with respect to any discoloration, it is suggestive of the possibility that white paints made with linseed oil have a less permanent colour than similar paints made with the other oils named. Tests showed that poppy seed oil, apart from being paler in colour when fresh, certainly has less tendency than linseed oil to discolour in this way, but a distinct, although slower, discoloration was perceptible under comparable conditions, the change in colour being still less obvious, although yet distinct, in the presence of a pigment. The especial tendency of linseed oil to discoloration is masked more effectively by white lead than by zinc oxide, doubtless because of the greater covering power of the former pigment, but even with a mixture of white lead and linseed oil the gradual development of the yellow coloration is observable, the possibility of the colour change being due to external

causes being again excluded by the occurrence of the change in an atmosphere of carbon dioxide in a sealed glass tube. The more feeble covering power of zinc oxide naturally causes the alteration of the colour of the medium to be more perceptible.

As to the nature of the chemical change underlying the alteration in colour, the experiments now described give no explanation other than that it is apparently independent of the well-known phenomena of oxidation and polymerisation of the oil. Probably some minor ingredient of the oil other than the glyceride mixture which forms the main constituent is to be regarded as the cause of the trouble, but further investigation is necessary before any definite conclusion can be drawn in this direction.

DISCUSSION.

The CHAIRMAN agreed with Dr. Twiss that the cause of discoloration lay in the oil and not in the pigment. Some time ago he had occasion to remove black paper coverings from varnished white enamels. One of the varnished coatings contained a high percentage of oil, while the other contained a large proportion of gum. The former showed marked discoloration. He inquired whether in Dr. Twiss' investigation traces of manganese had been present, because he was inclined to think that the colour changes might be due to the presence of manganese salts in the oil.

Mr. F. H. ALCOCK suggested that the discoloration might possibly be due to the presence of alkali. His view was that the yellowness of good quality putty was due to the causticity of the chalk. To neutralise the yellowness painters used a little blue.

Mr. L. P. WILSON enquired whether the experiments were made with a pure raw linseed oil or whether a boiled oil had been used. If this were so, it might supply the answer to Dr. Morrell's question. Manganese in minute quantities had a great colouring effect, and it was most evident, of course, when the manganese salts were dissolved in turpentine.

Mr. G. S. HEAVEN stated that in the factory with which he was concerned the white paint showed, on the whole, little discoloration; but when used to paint an imitation uralite it did not dry readily, and it showed a marked yellow coloration. The effect was, however, different on the various panels, but he noticed that a slight yellowing disappeared on exposure to light. He regarded the preliminary darkening, which disappeared on exposure to light, as being due to the linseed oil. He believed other colour evidences were due to free lime in the cement of the uralite. Mineral oil, in place of linseed oil or admixed with linseed oil, had also caused yellowing, but it was not well marked, and did not disappear on exposure to light.

Mr. G. H. HOWSE said that in investigations upon the discoloration of white paint which he had been carrying out for some years it had been found that no pigment or medium gave similar results in various parts of the country. Varying degrees of blackening and discoloration were observed with the same paints, including mixtures made with long oil, short oil, all-gum, spirit, gelatin, and water-glass media.

The action of radium and radioactive bodies as displayed in the spintharoscope, in which zinc sulphide was the substance acted upon, suggested that radioactivity had a good deal to do with the discoloration of white pigments, or, rather, upset the balance of colours which produce a white effect. He had therefore carried out an extended research with an ultra-violet lamp, and the results of these experiments led him to

assume that radioactivity was a factor to be considered, although he had not arrived at any definite conclusion in the matter.

Dr. Twiss, in reply, stated that as not only the "boiled oils" but also the raw oils showed discoloration of the type described the discoloration in question was not due to the presence of lead, and also that as the darkening was rather more rapid in an atmosphere of carbon dioxide than in the air it was exceedingly unlikely that the change in colour could with any degree of probability be attributed to the presence of alkali. In the case of the behaviour of a white paint referred to by one speaker, which contained a zinc oxide pigment and a cobalt drier and showed an especial tendency to darken in certain parts which were liable to be subject to the action of lime, it appeared quite possible that the discoloration might have been due to the formation of cobalt sulphide by the action of zinc sulphide present as impurity in the zinc oxide on the cobalt compound under the influence of the lime. With reference to the suggestion of the possibility that the discoloration could be attributed in some way to a radioactive effect rather than to a chemical change, Dr. Twiss was of the opinion that, whether induced by mere gentle heating or by the influence of radioactive substances, the alteration in colour was the outward manifestation of a chemical change in the medium of the paint.

THE TRANSFORMATION OF METHYL α -ELAEOSTEARATE INTO METHYL β -ELAEOSTEARATE.

BY R. S. MORRELL, M.A., Ph.D., F.I.C.

In continuation of the investigation of the properties of thickened drying oils Chinese wood oil (tung oil) was examined, following the methods described in a former paper (Morrell, this J., 1915, 105). The problem is simpler than in the case of linseed oil owing to the fact that tung oil contains a smaller number of component unsaturated glycerides.

The mode of investigation was to thicken the oil at 240° C. for 20 minutes until it commenced to set, and after rapid cooling to remove the polymerised part by treatment with acetone. The thickened oil had a specific gravity 0.9638 (15° C.) and a molecular weight (in benzol) of 1431; $[GIX]_D^{25} GIX$ requires 1317. The original oil had sp. gr. 0.944 and $n_D^{20} = 1.5171$ (12.5° C.). The value obtained for the molecular weight would confirm the view that half the oil consists of polymerised molecules. After extraction with acetone the soluble portion (41.5%) was found to have the following constants:—Iodine value 106.3 (1½ hrs.): sp. gr. 0.954 (11.5° C.), mol. wt. 876, $n_D^{20} = 1.5144$ (11.5° C.). The insoluble portion (47.5%) was a very viscid substance, therefore the iodine value alone was determined; this was found to be 104.3 (1½ hrs.). Treatment of the acetone-soluble part with sodium methoxide (Bull's method) gave a methyl ester, sp. gr. 0.9159 (10° C.), $n_D^{20} = 1.4958$ (10° C.), mol. wt. (in benzol) 300; iodine value 151.8 (1½ hrs.), 178 (6 days). $C_{18}H_{33}O_2CH_3$ requires mol. wt. 294; iodine value 173. The portion insoluble in acetone was likewise transformed into a methyl ester, sp. gr. 0.926 (12° C.); $n_D^{20} = 1.4950$ (12° C.); iodine value 138 (1½ hrs.), 168 (6 days); mol. wt. (benzol) 393.

Mention must be made of the iodine values obtained; in the case of the soluble and insoluble glycerides the values are too low and too high respectively and the methyl esters give normal values only after long contact with Wijs' solution.

The action of the sodium methoxide destroys

polymerisation almost entirely, a fact noticed in a previous paper (*loc. cit.*). The methyl esters from the portions soluble and insoluble in acetone respectively were fractionated under reduced pressure (10 mm.). The first methyl ester gave a non-volatile residue (33%) with mol. wt. (benzol) 481, and the distillate (59.7%) came over between 200° and 219° C. (iodine value 143–160, mol. wt. (benzol) 284.71). On redistillation 92% passed over between 209° and 221° C., corresponding to 55.3% of the original ester. The distillate had sp. gr. 0.900 (12° C.) and $n_D^{20} = 1.4842$ (12° C.).

The purified ester on saponification in the cold gave a good yield of an acid, m. pt. 66°–69° C., which on thrice recrystallising from 60% alcohol gave β -elaeostearic acid, m. pt. 71°–72° C., iodine value 172. On ultimate analysis 0.1196 gm. gave 0.3398 gm. CO_2 and 0.1204 gm. H_2O : C = 77.49, H = 11.2%; $C_{18}H_{33}O_2$ requires C = 77.14, H = 11.42.

The methyl ester from the portion insoluble in acetone was treated in the same way with the same results in almost every detail, except that the molecular weight of the non-volatile residue after the first distillation was 716. The acid obtained after saponification of the redistilled methyl ester at the ordinary temperature was β -elaeostearic acid, m. pt. 71°–72° C. (0.136 gm. gave 0.3765 gm. CO_2 and 0.130 gm. H_2O : C = 77.43, H = 11.0%; $C_{18}H_{33}O_2$ requires C = 77.14, H = 11.42%). The iodine value of the acid was 172.8. The properties of the fractionated methyl esters from the soluble and insoluble forms are practically identical. There are none of the complications occurring in olive, poppyseed, and linseed oils with their mixed and variable glyceride molecules. It is a straightforward case of polymerisation in which the complexes are broken up by removal of the glyceryl radicle. At what stage the stereo-isomeric change occurred had to be decided: it might have occurred during the thickening of the oil or during the distillation of the methyl ester. Sodium methoxide might be a factor, but this was very unlikely. In the saponification of the non-distilled methyl ester there was always a large amount of oily acid as impurity so that it was not possible to obtain a sufficient yield of a crystalline acid, α or β , to decide which was present in predominant quantity. Examination of the cerium salt from the undistilled methyl ester obtained from the acetone-soluble part of the oil showed that α -acid was present almost entirely and no β -acid. Cerium α -elaeostearate is completely soluble in ether but cerium β -elaeostearate is insoluble (Morrell, Chem. Soc. Trans., 1918, 113, 111; see this J., 1918, 130 A).

It was found that Chinese wood oil yielding the α -acid in good quantity was transformed into the methyl ester in the manner previously described. The methyl ester was fractionated under identical conditions and gave a slightly smaller non-volatile residue (15%). The methyl ester was not identical with those described previously and indicated a slightly simpler molecule, but the acid obtained was β -elaeostearic acid, m. pt. 71°–72° C., C = 77.7, H = 11.1%.

The conclusion drawn is that stereo-isomeric change has occurred during the distillation of the ester. Comparison of the physical properties of the crude and redistilled methyl ester showed the former to possess a slightly higher sp. gr. (0.9022 against 0.899 at 16° C.) and n_D^{20} (1.516 against 1.496), but the iodine value shows no marked difference. It is evident that during the rapid thickening of the wood oil (20 minutes at 240° C.) no isomerism has occurred, but stereo-isomeric change ensues on distillation of the methyl ester.

This conclusion does not invalidate the suggestions made as to isomeric changes occurring during the polymerisation of linseed oil, because the

evidence brought forward was very decided; moreover the length of time necessary to produce thickening in the two cases is vastly different (20 minutes against 28–60 hours). The fractionation of the methyl esters takes considerable time, during which the esters are maintained at a high temperature. The fact of the formation of the β -ester confirms the view that molecular rearrangements are most probable when drying oils are heated, moreover the quantities of the non-volatile residues in the distillation of the methyl esters obtained from thickened and non-thickened wood oil are different, which is a fact worthy of remark.

DISCUSSION.

Dr. D. F. TWISS asked regarding the polymerisation of Chinese wood oil what proportion of the oil which had been heated just short of "setting" remained soluble in acetone, because he was of the opinion that even in the firm gelatinised oil a considerable percentage still could be removed by extraction with this solvent. He also asked whether the structural change from the α to the β acid was in the same direction as that induced in oleic acid by nitrous acid.

Dr. E. B. MAXTED stated that with regard to the melting point the result varied, apparently depending on temperature when hydrogenated. He wondered whether any change could have taken place in the acid.

Mr. G. H. HOWSE inquired if Dr. Morrell had taken any records as to the polarity or refractive index of the acids before and after polymerisation. Would any such records help to determine the direction in which the changes mentioned occurred?

Mr. H. G. EVANS pointed out that in the treatment of the oils there were three processes—(1) polymerisation, (2) formation of esters by sodium methoxide, (3) distillation. Dr. Morrell mentioned only the first and last as likely to cause changes in the position of double bonds. Was it possible that the sodium methoxide used in the formation of the esters could have any effect on the double linkages?

Dr. MORRELL in reply stated that the percentage of oil insoluble in acetone in the case of thickened linseed oil was 50% and likewise the percentage of acetone-insoluble oil from thickened Chinese wood oil was 50%. Nitrous acid did not change α -elaeostearic acid into the β modification, but the transformation readily occurred in sunlight. It was quite possible that sodium methoxide might be a factor in causing stereo-isomeric change. The question of ring-formation on heating was difficult to answer. From the work done on thickened linseed oil the evidence was inconclusive but was generally contrary to ring-formation.

MR. A. T. SMITH IN THE CHAIR.

NOTES ON OIL PITCH.

By W. MANSBRIDGE.

Pitch, as met with in commerce, is as various in its properties as the raw materials from which it is produced, and with each variety, especially mineral oil pitches, there are a number of distinct grades each intended to meet some particular requirement. As an instance, one refinery lists no less than fourteen grades, all produced from the

same crude oil and only differing materially in melting point and hardness.

Blast furnace and coke oven pitches are not so well known as that produced from coal tar, but they have similar properties and uses, as one would expect seeing that they are derived from the same material—coal—in each case; they are, however, harder, more brilliant, and freer from smell and can be employed where coal tar pitch would be objectionable.

Next in order of magnitude of production is the pitch made from mineral oil. Its importance dates from the discovery of the Texas oil fields, for although oil pitch, as it is now often called, was made from certain crude petroleum, the quantity was not large and its consistence hardly entitled it to be called pitch.

Later the Galician and Rumanian oil fields were developed and as the oils from both these fields have an asphaltum base they give a good yield of pitch to the refiner. Large quantities also come from Mexico and California, the toughness of the former variety at low temperatures making it exceptionally suitable for road construction and similar work.

It was at first difficult to find a market for the very large quantities of pitch made from the Texas oil and probably many thousands of tons were burned under the stills. In time, however, its valuable properties were recognised and an extensive field was opened up for its use. The yield varies according to the melting point desired and the quality of the crude oil. In a general way commercial grades may be said to follow the melting point, and as this characteristic rises so also the other physical tests are modified; the flash point is raised, the penetration number is lowered, and naphtha-soluble bitumens diminished in amount. The table on p. 183 T, which relates to the products of a single refinery, shows this very well and may be taken as a type of what is obtained from a crude oil with bituminous base.

Oil pitches are now used to a very large extent, especially in America, for architectural, road-making, insulating, and general waterproofing purposes, and as anti-corrosive paints or coatings for steel work. In England they have to compete with cheap coal tar pitch which fulfils many of the conditions required and at about one quarter the price in normal times. Notwithstanding this, oil pitches have found ever-increasing favour for the better classes of work. The properties of toughness and flexibility at low temperatures, resistance to acids and alkalis, the tenacity with which they adhere to metallic surfaces, their high insulation resistance, and in some cases brilliancy of fracture, make them specially useful in certain industries. Some crude oils yield a hard, brittle pitch almost entirely soluble in turpentine and substitutes, which by judicious blending, can be used in high class black Japans such as bicycle enamel.

Closely allied are the mineral bitumens or asphaltum, properly so called, gilsonite, manjak, Syrian, Cuban, and Colombian. Hard, glossy, very black, soluble in all the spirits and oils used for the purpose, these are pre-eminently materials for the varnish maker, and enter into the composition of the highest grade of Japan and black enamel whenever a beautiful finish is desired. Asphaltum is hand-picked and often sold with a guarantee as to its percentage of ash.

Stearine pitch. This term was formerly restricted to the residue obtained in the distillation of tallow and palm oil but it has since been extended to include any pitch made from fatty acids, except in cases where a modification of the name designated some advantage. Stearine pitch is now principally used, the hardest varieties

pure, the softer sorts after blending with an asphaltum, such as gilsonite. In some form of varnish making, as it is entirely soluble in turpentine, petroleum spirit, etc. Some varieties, such as the harder kinds yielded by drying and semi-drying oils, require special treatment to obtain complete solution.

Cottonseed pitch although often sold as stearine pitch stands in a class by itself. This material is made by distilling the cottonseed black grease prepared from the "mucilage" obtained in refining crude cottonseed oil. The mucilage, which is a mixture of saponified fat, colouring matter, and neutral oil, is treated with cheap mineral acid to decompose the soap, and the resulting black grease is washed and distilled. The quality of the pitch depends upon the kind of crude oil, the skill of the refiner, and the particular methods of distillation. If the crude cottonseed oil has been crushed from American decorticated seed the black grease is very free from colouring matter, high in neutral oil, and gives on distillation an elastic rubber-like pitch which can be vulcanised. On the other hand the pitch from Egyptian undecorticated seed is very hard, brittle, and difficult to use without special treatment. When crude unrefined cottonseed oil is distilled the pitch obtained is elastic in the highest degree, emerging from the still as a spongy mass very similar in appearance to the rubber sponges of commerce.

Elastic cottonseed pitch after vulcanisation is ex-

tensively used in electric cable-making. Such cables are, however, apt to "decentralise" and eventually to break down. If laid in cold, frosty weather the insulation, having become brittle, cracks as the cable is unwound from the drum and breakdown occurs from that cause. The harder kinds of cottonseed pitch are extensively used in the manufacture of waterproof paper, and are applied in the form of a varnish by suitable machinery.

Wool pitch, from crude brown wool fat, furnishes an excellent material for the lubrication of the bearings in hot rolling mills in steel works, etc. When melted, even at a high temperature, it remains viscid and keeps its lubricating power under very severe conditions of heat.

Ozokerit and ceresin pitch are employed as "finishing wax," as in the form of heel-ball; suitable qualities burnish well and take a high polish; they are also useful for many purposes of the electric cable manufacturer and for core vent wick as used by ironfounders.

Bone pitch comes from the tar obtained in bone black making; it is the blackest of all the pitches and is used by the varnish maker to deepen the colour of his enamel.

Commercial testing and analysis of pitch.

Melting point. There are three methods employed for this test, none of which can be said to indicate

the true melting point, but rather the point at which the sample under examination becomes soft enough to flow. In one of these, known as the Wendriner method, itself an improvement on the procedure of Kraemer and Sarnov, the movement is assisted by a weight of mercury. A convenient and useful way to carry out this test, and one used by the author for many years with good results, is as follows:—

A small piece of the pitch, weighing about 6 grms., is taken from a clear interior surface of the sample and attached to the bulb of a thermometer, by slightly warming the substance and pressing it on the glass so that it adheres firmly. Not more than one-third of the bulb should be covered. If the pitch has to be made very hot to effect this it should be allowed to become cold again before proceeding with the test. The thermometer is arranged in a 1-inch boiling tube over an ordinary argand burner (not argand Bunsen burner), in such a way that, the tube being vertical, the sample is in the centre of the tube and $1\frac{1}{2}$ in. from the bottom. The thermometer passes through a cork which closes the tube, and which has a second hole bored through it as a vent for the heated air. The tube is held vertically over the burner by means of a clamp fixed to a retort stand, a piece of wire gauze interposed between the burner and the glass tube serving to moderate the heat and support the tube.

The operation is commenced by so regulating

the burner that only a very small blue flame is visible, and as required the flame is gradually raised, until the pitch fuses. When the pitch reaches the bottom of the tube, either as a detached drop, or as a viscid thread still remaining attached to the mass on the thermometer bulb, the temperature is noted and recorded as the melting point of the pitch.

The speed with which the test is conducted may greatly affect the accuracy of the result, and in order to ensure uniformity the author allows the temperature to rise at the rate of 3° F. per minute for pitch melting below 140° F. and at 5° F. per minute for samples melting above 140° starting from the temperature of the room. Usually the operation takes about 20 minutes.

Some operators use what is called the "cube" method; in this a 1 cm. cube of the material is suspended on wire in an air bath, the temperature of which is raised at the rate of 5° F. per minute. The bulb of the thermometer is placed at the side of the cube and within one millimetre of, but not touching, the sample.

The "melting point" is most usefully employed to discriminate between different grades of the same kind of pitch, though valuable information may sometimes be gained by the character of the drop. Some varieties melt more completely than others, or more suddenly, and yield a detached drop of liquid material while others give a viscid

string which only really melts on touching the hot bottom of the tube in which the experiment is conducted.

Solubility. A rough test for solubility can be made with a distillate of petroleum known as "White spirit," though lighter petroleum spirit will serve if used with caution. About 10 c.c. of the solvent is added, the thermometer lowered to the bottom of the tube, and the contents boiled. When thoroughly mixed or dissolved as the case may be, the whole is allowed to settle for a few minutes and the residue examined; its quantity and appearance are indicative of the procedure to be followed in a complete examination for solubility should such be required.

The general practice is to treat the sample with different solvents in succession, having in view the purpose for which the pitch is intended. This will determine the kind of solvent to be employed and in most cases it will be found that some may be omitted. Ordinarily, petroleum spirit (light motor spirit), "white spirit" (sp. gr. 0.785–0.800), 90% benzol, carbon tetrachloride, and carbon bisulphide are used, and in special cases turpentine or linseed oil. A good method of applying the solubility test is to take sufficient of the sample, as indicated by the preliminary rough trial above referred to (5 to 10 grms. is generally enough), and dissolve this in the solvent by first melting and then boiling, when practicable with enough of the solvent to give a fairly thin solution; this is then transferred to a stoppered graduated measure and made up to 50 c.c. or 100 c.c. as convenient. The solution is allowed to stand overnight; in the morning the clear supernatant liquid can be decanted and if a portion be evaporated the residue of soluble bitumens may be examined. The precipitate is shaken with a further quantity of the solvent, transferred to a weighed filter, washed until the filtrate is no longer coloured, dried, and weighed. A Soxhlet extractor is often recommended for this test but the author prefers the above procedure, and can often obtain sufficient information from an inspection of the graduated measures in the morning to serve the purpose in view.

Penetration test. This test is more frequently used in America than in this country, chiefly by the producers of mineral oil pitch to grade their products. The New York Testing Laboratory penetrometer and the Dow penetrometer are the forms in general use. Neither of these instruments is regarded in this country as being satisfactory for the purpose and efforts are being directed towards designing an improved pattern capable of yielding better results. In this test a weighted needle is so arranged that it bears upon a portion of the sample kept at a stated temperature. The needles are of various sections and the load can be varied; the results are expressed by the distance in decimillimetres which the selected needle enters the pitch in say 5 seconds with 100 grms. load at a specified temperature.

Other tests. The flash point, open and closed test, and the fire test, are often called for and may be determined in the same way as for mineral oils, using the Gray flash point apparatus or the Pensky-Martens tester.

The specific gravity is conveniently obtained, with sufficient accuracy for ordinary purposes, by cutting a cube from the centre of a block of the sample with a hot, thin-bladed knife and adjusting a solution of glycerin at 60° F. so that the cube when immersed in it neither rises nor falls; no adhering air bubbles are allowed and the sample must be free from cavities. The specific gravity of the glycerin is then taken in the ordinary way. Owing to the difficulty of wetting the pitch this will be found quicker than by weighing in water

as is usually done with minerals. For samples lighter than water a mixture of water and methylated spirit may be used, but this will very seldom be required.

Saponification and titration of the fatty acids in stearine pitches may be carried out by boiling to dryness 30 grms. of the sample with 20 c.c. of methylated spirit and 10 c.c. of a 25% solution of sodium hydroxide; the partially saponified mass is then dissolved in hot water, boiled with dilute sulphuric acid until the soap is decomposed, the pitch layer washed twice, or until free from mineral acid, with water (by boiling), dried, and titrated with $N/2$ sodium hydroxide, using alkali-blue as indicator. The results are calculated to oleic acid.

The volatilisation test, sometimes specified, is carried out by heating a convenient quantity, e.g., 20 grms., in a circular vessel $2\frac{1}{2}$ inches in diameter at the surface of the melted pitch, for 5 hours at 350° F. and noting the loss.

Sulphur is determined by the well-known lime or magnesia method, using two crucibles, one inverted in the other, for the ignition.

The electrical tests required by the cable manufacturers call for special apparatus not available in the ordinary works laboratory.

Scheme for the examination of pitch.

The want of a simple, trustworthy scheme for the examination and identification of pitch must often have occurred to the works chemist or engineer when in search of suitable material or to control supplies. In order to supply this need a description is given below of the methods followed for many years when dealing with samples of unknown origin. It is necessary, however, to point out that the scheme is not intended, except in the most general way, to apply to mixtures; such may, and often do, present problems of extreme difficulty, as in the case of proprietary articles which are specially compounded with that object. If this limitation be kept in mind, the scheme will be found very helpful in most cases.

The scheme is based on the separation of pitches into two classes by their behaviour when treated with alcoholic soda or potash solution. These two groups are then subdivided according to the indications given by treatment with "white spirit" and finally identified by special tests or characters. "White spirit" has been chosen because it can easily be obtained and it is not so volatile as the light petroleum spirits, so that the sample can be more freely boiled; further, if it is not at hand ordinary petroleum burning oil will give nearly the same results. The grade of "white spirit" recommended should have a boiling point near to 140° C. and a specific gravity between 0.785 and 0.8.

The information obtained by working through the scheme will naturally be followed by the special analysis necessary to decide whether the sample answers any particular specification; these requirements are too varied to be dealt with in these notes.

The sample is boiled with alcoholic soda solution until nearly dry; this is best done in a 4 or 5 inch porcelain basin.

Section 1. The sample is wholly or partly saponified. Stearine pitch, all varieties. Woolgrease pitch. Bone pitch.

Section 2. No saponification takes place. Coal tar group. Mineral oil group. Natural asphaltums. Ozokerit pitch. Wood tar pitch.

Section 1. Boil about 0.6 gm. in 10 c.c. of white spirit, allow to settle for a few minutes, decant or filter, and examine the residue.

The substance dissolves—

(a) Stearine pitch from all non-drying fats.

(b) Wool grease pitch. This may be recognised by its tenacity when nearly melted and by the presence of cholesterol.

The substance partly dissolves—

(a) Pitch from drying or semi-drying oils and fats, including soft cottonseed pitch. This is usually oxidised when testing melting point. The insoluble portion is in broken films or scales which powder when rubbed between the fingers.

(b) Bone pitch, giving a characteristic odour of bones when heated.

The substance is insoluble or nearly so—

(a) Hard cottonseed pitch (melts in flame).

(b) Elastic cottonseed pitch, sometimes called "rubber" pitch. Does not melt in flame, will stretch and return.

Section 2. Treat with white spirit as in Section 1.

The sample dissolves—

(a) Soft mineral oil pitch, of treacly consistence or very plastic.

(b) Natural asphaltums, when free from mineral matter (ash). Hard and brittle with brilliant fracture.

The sample is only partly soluble—

(a) Nearly all mineral oil pitch. This is more or less plastic and has very low ash, usually below 0.3%.

(b) Natural asphaltum when containing mineral matter. Hard, brittle and can be powdered; ash high, often visible with a lens in the sample.

(c) Ozokerit pitch. Fracture rough; waxy when heated; will burnish with a warm, bright iron.

(d) Trinidad pitch. Plastic to brittle according to melting point; hard varieties very dull rough fracture, with high ash, not visible.

The sample is insoluble; the spirit is coloured yellow and becomes highly fluorescent—

(a) Coal tar group, including blast furnace and coke oven pitch. These give a characteristic smell when heated.

(b) A few mineral oil pitches, which give an asphaltum smell when heated.

(c) Wood tar pitch, giving a woody smell when heated, like Stockholm tar.

of coal as a fuel have brought about the centralisation of lime-burning, and it is now more convenient for farmers to obtain their lime by rail from these centres. Besides, the use of grinding plant has led to the production of forms of quicklime and carbonate which are easier to handle and to distribute than lump lime.

During the last 50 years the practice of liming soils has fallen off to a very marked extent, and one of the reasons for this falling-off is the ignorance of many farmers as to the significance of the large number of factors responsible for the satisfactory growth of crops, and particularly the varied and essential influences of lime on the productivity of soils. After the introduction of artificial fertilisers it was much too commonly believed that liming could be neglected with impunity where such new manures were used.* Many artificers call rather for an increased use of lime.

Any one of the factors referred to may become a "limiting factor," and there is no doubt that over large areas in Yorkshire deficiency of lime in the soil seriously limits crop production.

Such soils are said to be "sour," and are recognised in the field by the setting up of certain conditions (not yet fully investigated) which affect the soil physically as well as chemically, and which are unfavourable to the growth of most cultivated crops as well as to useful micro-organisms such as the nodule organisms of leguminous plants, other nitrogen-fixing organisms (azotobacter), and the nitrifying organisms.

Heavy soils tend to become sticky and to set hard on drying owing to a deflocculation of the clay. Certain classes of weeds become troublesome, e.g., sorrel (*Rumex acetosa*), and on light land spurrey (*Spergula arvensis*); whilst cruciferous crops are commonly affected with "finger and toe." Most leguminous crops are particularly sensitive to "sour" soil conditions.

In the case of grass land, "sourness" of the soil gives rise to the formation of the well-known "mat" of undecayed organic matter which forms on the surface and does not become incorporated with the soil. Conditions become unsuitable for the more useful grasses, the places of which are taken by inferior grasses and weeds, which usually include sheep's sorrel, field wood-rush, heath bed-straw, and other typically moorland plants.

The soil itself shows a general deterioration which includes a reduction in the number of bacteria, and no doubt gives rise to the condition often spoken of by practical men as "dead."

Originally "sourness" was attributed to the presence of acid substances, partly mineral, but chiefly organic, and produced during the decomposition of organic remains in a soil deficient in bases, particularly lime. Many organic compounds of an acidic nature have been isolated from the "humus" of soils. Later this view was challenged on the grounds that most of the apparently acidic properties can be explained by the colloidal nature of the organic matter and the clay; whilst still more recently "sour" soils have been defined as those which are, for bases, "absorptively unsaturated."

A determination of the amount of calcium carbonate in the soil does not always reveal the true state of affairs, since two similar soils containing approximately equal and insignificant quantities of carbonate may behave very differently towards crops which are sensitive to "sour" conditions, and may respond very differently to dressings of lime.

* This is perhaps hardly to be wondered at since the production of artificers found soils generally well supplied with lime, so that for some time no deterioration was experienced, and a new generation of farmers had largely arisen before the trouble became acute.

Yorkshire Section.

Meeting held at the Queen's Hotel, Leeds, on
March 11th, 1918.

PROF. J. W. COBE IN THE CHAIR.

LIME, AND THE LIMING OF SOILS.

BY J. A. HANLEY.

Neglect of liming is the primary cause of the unproductive nature of large areas of land in Yorkshire, and the seriousness of the results of this neglect has been emphasised recently, firstly, by the dying off of many acres of grass in the West Riding—usually on coal-measures soils—and secondly by the difficulties attending the ploughing-out and other operations necessary to the conversion of grass into arable land in many parts of the county.

A good deal of evidence has been accumulated recently as to the "lime-requirements" of various types of Yorkshire soils, and the sources of lime available for the county.

Before the introduction of artificial fertilisers, lime and dung were the staple manures, but owing to the more restricted facilities for transport, lime had to be produced nearer the farms and the sources of fuel.

The rapid growth of other industries and the use

Soils which are definitely "sour" are not merely devoid of lime but they require the incorporation of a quantity of lime, sufficient, under natural conditions, to bring them to the point of saturation. Many methods have been introduced for the determination, in the laboratory, of this quantity of lime, which is known as the "*lime-requirement*."

In the Hutchinson and MacLennan method,* which has recently been applied to a large number of Yorkshire soils of different types, the soil is treated with a freshly prepared solution of calcium bicarbonate and a determination made of the lime absorbed. The method has always given results in close agreement with actual observations in the field and with field experiments.

The following is a list of a few results obtained with a variety of Yorkshire soils:—

However the "sourness" is induced, the ultimate effects on growth of crops, prevalence of weeds, etc., is the same.

Instances of "sourness" produced or increased by the use of sulphate of ammonia are common, and can be seen at many centres where manurial trials are carried out continuously; most marked results have been obtained on the light sandy soil of the Wheat and Barley Plots at the Royal Agricultural Society's Experimental Farm at Woburn, and also on the Meadow Hay Plots at the Leeds University Experimental Farm at Garforth.

The effects of smoke are very noticeable in many parts of the West Riding both on soils originally "sour" and on good soils which originally contained an ample supply of calcium carbonate.

The results of "lime-requirement" determina-

TABLE 1.

Lime-requirements of Yorkshire soils.

Type of soil.	Characteristics of soil and crops.	Lime-requirement, CaCO_3 required expressed as percentage of air dried soil.
Carboniferous limestone	Deep soils in district of high rainfall. Sorrel and woodrush prevalent in herbage.	0.2–0.3 % CaCO_3
Magnesian limestone	Rather shallow soils. Woodrush prevalent. Clover absent.	0.1 % CaCO_3
Chalk soils	Soil of variable depth. Coarse herbage on grass land; "finger and toe" in turnips on arable land.	0.1 % CaCO_3
Coal-measures soils	Heavy arable soil, difficult to till. Heavy grass land, woodrush, sorrel, and bent grass very prevalent; thick "mat."	0.4–0.5 % CaCO_3 0.5–0.6 % CaCO_3
	Lighter soils derived from coal-measures sandstones: grass and arable land.	0.25–0.4 % CaCO_3
Millstone grit soils	Good grassland, well limed. Unlimed portion of same field, poor grass with thick "mat"; woodrush, sorrel, and heath bedstraw (<i>Galium saxatile</i>) very prevalent. Semi-moorland sheep pasture with above-mentioned weeds and bilberry.	0.06 % CaCO_3 0.55 % CaCO_3 0.44 % CaCO_3
Moor grit soil	Reclaimed moorland in N.E. Yorkshire; very peaty and growing much ling.	0.78 % CaCO_3
Peaty alluvial soils (carr land)	Pasture field rapidly deteriorating; much sorrel, thick "mat," and large barren patches. Adjacent field ploughed out, 3 out of first 4 crops failed. Rather better carr land.	0.68 % CaCO_3 0.77–0.90 % CaCO_3 0.30 % CaCO_3
Boulder clay soils in West Riding	Grassland on which woodrush and sorrel are prevalent.	0.1 %–0.22 % CaCO_3
Chalky boulder clay soils in East Riding	Usually very little indication of "sourness."	Nil–0.05 % CaCO_3
Warp soils	Ditto.	Ditto.
Light sandy drift soils in Vale of York	Chiefly arable land. Spurrey a very common weed. Leguminous crops, barley, and turnips often unsatisfactory.	0.1–0.2 % CaCO_3

The above results were all obtained from samples taken on land typical of fairly large areas, under ordinary methods of cultivation, and outside smoky districts.

The "sourness" is due to the neglect of liming soils either originally deficient in lime, *e.g.*, coal-measures or millstone grit, or from which the lime has been washed out by rain, *e.g.*, limestone soils and many of the drift soils.

The inevitable loss of lime by leaching is augmented

(1) By the continuous use of acid fertilisers, particularly sulphate of ammonia.

(2) By the presence of a smoky and acid atmosphere.

tions on soils affected by smoke are given in Table 2.

In the case of the Don Valley soil which was originally well supplied with calcium carbonate, the deterioration appears to have taken place very rapidly. The calcium carbonate has been leached out to a depth of about 15 inches; the bottom 3 or 4 inches of the second 9-inch sample contained plenty of calcium carbonate.

"Sourness" is corrected by dressings of calcium oxide, hydroxide, or carbonate (or in some cases the corresponding compounds of magnesium, see later).

It is obvious that, for agricultural purposes, the presence of small quantities of impurities, provided that they are completely oxidised or in an easily oxidisable form, and are otherwise non-

* J. Agric. Sci., 7, 75.

TABLE 2.

Lime-requirements of soils affected by smoke.

Type of soil and locality.	Characteristics of soil and crops.	"Lime-requirements." CaCO ₃ required, expressed as percentage on air-dried soil.		
		1st 9 ins.	2nd 9 ins.	3rd 9 ins.
River alluvium from Don Valley near Mexboro'	Derelict grass land which 10 years ago was good pasture.	0.53 %	0.26 %	Nil.
River alluvium from Calder Valley near Dewsbury	Derelict grass land, full of sorrel, with patches of creeping Yorkshire fog. Covered with a mat of dead and charred vegetable matter.	0.48 %	0.19 %	0.17 %
River alluvium from Calder Valley near Wakefield	Rapidly failing grass: thick "mat": much sorrel and large patches of creeping Yorkshire fog: many barren patches.	0.34 %	0.09 %	---
Coal-measures soil at Halifax	Derelict grass land. Barren arable land, corn crop a failure: grows nothing but stunted sorrel.	0.57 % 0.62 %	---	---

poisonous to plants. Is of little consequence so long as the price of the lime is consistent with the percentage of CaO and the cost of transport and application of the required dressing of lime.

It is, however, essential that an agricultural lime should dissolve as quickly as possible in rain or soil water so that it may come into contact with every part of the surface soil. This can only be attained by the thorough incorporation of a finely divided material with the soil.

In the case of quicklime extreme fineness is obtained by slaking, and one of the great advantages of ground quicklime is that it allows of mechanical distribution, and by slaking in the soil allows of still more thorough distribution during subsequent cultivation.

Lump lime is usually slaked in heaps in the field and the slaked lime spread with shovels; this allows of effective distribution only if the dressing exceeds 2 tons per acre.

In the case of carbonate of lime all the disintegration must take place during grinding, but when this is effectively carried out so that about 80% will pass a sieve with 100 meshes per linear inch, it gives results equal to those obtained with quicklime. This applies also to the different forms of waste carbonate of lime obtainable from some works.

The following tables show the first year's results obtained from experiments at Selby and Garforth in 1917:—

TABLE 3.

Effects of quicklime and carbonate of lime on a light soil at Selby (initial lime-requirement 0.2% CaCO₃).

Treatment.	Weight of turnips per acre.	Percentage reduction in lime-requirement after 1 year.
No lime	4 tons 18 cwt.	0
2 tons undried ground chalk, spread with shovels	10 tons 12 cwt.	39 %
5 tons 14 cwt. ditto, ditto	10 tons 4 cwt.	39 %
2 tons dried ground chalk, mechanically distributed	11 tons 6 cwt.	52 %
1 ton ground quicklime, mechanically distributed	11 tons 11 cwt.	26 %

The undried ground chalk used was waste material from whitening manufacture. It contained about 15% moisture and was somewhat lumpy; the lumps, however, broke down easily on drying.

The dried ground chalk passed through the distributor at the rate of 10 cwt. per acre, so that the whole of the plot was passed over 4 times to complete the dressing of 2 tons per acre. An extremely uniform distribution was thus obtained.

TABLE 4.

Effects of different dressings of quicklime and carbonate of lime on a Garforth soil (initial lime-requirement 0.3% CaCO₃).

Treatment.	Percentage reduction in lime-requirement after 1 year.
No lime	0
Half lime-requirement of quicklime	17 %
Full ditto	34 %
Double ditto	37 %
Half lime-requirement of calcium carbonate	19 %
Full ditto	36 %
Double ditto	30 %

The land was not cropped; the corresponding dressings of quicklime and carbonate of lime reduced the "sourness" to the same extent in every case.

The effect of quicklime is, in one respect, different from that of calcium carbonate; dressings of quicklime in excess of the lime-requirement of the soil produce partial sterilisation effects.*

Calcium hydroxide, sold as hydrated lime, is occasionally obtainable. Its main advantage is that it can be stored and applied at the farmer's convenience.

There are five varieties of limestone quarried and burnt in Yorkshire, viz., Carboniferous (Mountain), Lower Magnesian, Upper Magnesian, Oolitic, and Chalk. With the exception of the Lower Magnesian limestone, there is very little to choose for agricultural purposes between the best samples of lime from the different sources.

The magnesian limestone requires special consideration not only on account of the high magnesia content of the Lower Limestone, but also because of the important position of its outcrop. It occupies a belt extending from Nottinghamshire to the Durham coast, and passing through the middle of Yorkshire, where it adjoins some of the "sourest" soils in the county.

The Upper Magnesian Limestone is fairly pure.

* Hutchinson and MacLennan, J. Agric. Sci., 6, 302.

* Samples of lump lime.

and usually contains less than 2% of magnesia, but the Lower Limestone, separated from the Upper by a bed of red marl, although variable in composition, usually approaches a true dolomite.

In Durham the middle red marl thins out, but the marked differences in the magnesia content of the different beds of Magnesian Limestone are maintained.

That the two types of limestone yield agricultural limes of different qualities was recognised in the eighteenth century, and Tennant† published in 1799 the results of an investigation into the causes of the harm done to certain land by applications of lime with a high magnesia content.

Magnesian lime has been, and still is, used with great success on some types of soils, and such cases which have been brought to the notice of the author have usually occurred on heavy, "sour," coal-measures soils, but one marked result was also obtained on a heavy alluvial soil with a small lime-requirement, where a dressing of 2½ tons per acre of Warmsworth lime made a great improvement in the crops and in the texture of the soil.

Where complaints of the bad effects of magnesian lime have been made the soil has usually been either a light sand or a soil overlying the magnesian limestone rock.

An excess of magnesia in the soil is toxic to most cultivated plants, and such toxicity can be corrected by dressings of a pure lime.

Magnesium oxide or carbonate will improve soils where "sourness" is the factor limiting production. Equivalent dressings of CaO, MgO, CaCO₃, and MgCO₃ were given to a "sour" Garforth soil with the results shown in Table 6.

MgO ..	166	28%
MgCO ₃ ..	150	22%

Magnesian lime is never preferable to a pure lime for agricultural purposes, but in view of its effectiveness in correcting "sourness" in soils, and of the convenient position of its outcrop, it is desirable that full use should be made of it for initial dressings on some of the very "sour" coal-measures and millstone grit soils of the West Riding, particularly where short transport would reduce considerably the cost of such applications.

Magnesian lime should be used only in moderate dressings (not exceeding 3 tons per acre on heavy

land) and should not be used on very light soils, soils containing already a high proportion of magnesia, nor on soils not definitely "sour."

There are three forms of lower grade lime usually available at the limestone quarries:—

(1) "Seconds" or small lime—the screenings left after the selection of the best lump lime. This material is usually sold for agricultural purposes, and like ground lime can be applied direct and allowed to slake in the soil. The composition is variable, but analyses of four samples, all from the Mountain Limestone, are given in Table 7. The quality is obviously determined mainly by the quantity of coal ashes, etc., present.

TABLE 7.

Analyses of "seconds" or small lime.

	%	%	%	%
CaO ..	88.51	75.52	60.38	59.59
MgO ..	1.28	1.24	—	—
Fe ₂ O ₃ and Al ₂ O ₃ ..	1.98	11.18	11.03	18.66
Insoluble ..	5.64	8.18	17.18	11.45
CO ₂ ..	1.12	1.13	2.65	2.07
Moisture, etc.	1.47	2.75	8.76	8.23

(2) *Lime refuse*—usually a mixture of hydroxide and carbonate. A sample from a Lower Magnesian Limestone quarry showed on analysis CaCO₃ 10.15, MgCO₃ 11.76, Ca(OH)₂ 31.23, Mg(OH)₂ 24.82, Fe₂O₃ and Al₂O₃ 3.38, insoluble 7.65, moisture, etc., 10.91%.

(3) *Limestone dust*—produced during the breaking up of the rock. Such material is usually too coarse to be of much use, but if finely ground would be extremely useful to agriculture.

The production of lime for agricultural purposes has dropped considerably during the war, whereas there has been an increased demand from other essential industries. A large amount of the lime used in industries is, when "spent," merely regarded as waste material and consigned to the tip, although it is often still in a state quite suitable for application to the land.

"Spent" lime from industries usually contains some calcium hydroxide, but consists chiefly of calcium carbonate, so that thorough distribution of a finely divided material is necessary if the most effective use is to be made of such lime. The wet and sticky condition of most of the spent limes renders effective distribution impossible, but when dried most of them pulverise easily. The farmer has no conveniences for drying, and is only too frequently short of space where such lime can be stored under cover; moreover "spent" lime with a high percentage of water will not bear the cost of any appreciable transport. A second objection to the use of some forms of "spent" lime is their liability to contain substances poisonous to plants. Such poisonous substances, e.g., salts of arsenic and copper, may retain permanently their poisonous nature, and lime containing these should on no

† S. Tennant, Phil. Trans., 1799, 305—314.

account be used; but others, e.g., organic compounds from tar distillation or inorganic compounds such as sulphides, sulphites, and ferrous salts, are either lost by volatilisation or are converted into harmless compounds on exposure to air, and lime containing these may be used after some months' exposure to weather. In such cases autumn application of the lime is always desirable.

Some of the waste limes examined include:—

Waste ground chalk from chiting manufacture. This is usually available in the East Riding. When dry it contains about 96% CaCO_3 , but owing to its being stored in the open it is liable to contain a considerable percentage of water. It has been tried experimentally at Selby (see Table III.), and has also given good results in other parts of the county.

"Spent" lime from re-causticising soda is in a fine powdery condition when dry, and where the amount of soda contained in it is not excessive, it is quite suitable for application to the land.

Carbonate of lime from water-softening plant is also in a finely divided state and has been used successfully.

Burnt sewage may contain 60% of finely divided calcium carbonate and has been used successfully on lawns on "sour" soils near Leeds.

Gas lime has been used by farmers and gardeners for such a long time that the risks attending its use are well known. It contains a number of incompletely oxidised compounds which become harmless after a winter's weathering. A number of other "spent" limes such as carbide waste (which is at present being tried experimentally at Garforth and elsewhere) should be treated in the same way and never applied to land immediately before the sowing of a crop.

"Spent" lime from tanneries and fellmongeries may in some instances possess all the disadvantages to which waste limes are liable. It is wet and sticky when fresh, always contains sulphides, and occasionally, where arsenic sulphide is used for unhairing, arsenic as well. The sulphides are quickly converted into harmless sulphates when the lime is spread out, but tanners' lime containing arsenic should never be used.

In order that the most efficient use may be made of waste or "spent" lime it should, whenever possible, be supplied by firms in a condition suitable for application to the land, i.e., it should be dry and powdery. It should be cheap in comparison with lime of similar quality obtained directly from the quarries, and since the percentage of CaO would never be high it should be used chiefly in the neighbourhood of the works producing it so as to eliminate as much as possible the cost of transport.

Industrial districts in Yorkshire coincide for the most part with districts where the soil is naturally "sour" and badly in need of lime, and the crops in these districts would be greatly improved if more of the waste lime from industries were applied to the soils affected. There are probably many sources of waste lime not mentioned above, and any information about such lime would be of great assistance to agriculturists at the present time.

DISCUSSION.

The CHAIRMAN asked, in relation to the use of lime along with sulphate of ammonia, whether there was any escape of liberated ammonia from the soil. Another question would relate to tests applied to lime in the laboratory to find out how far it was suitable for application. The value of lime for water-softening was not strictly determined by its chemical composition, and it was worth while to find out how much of the lime became available as a softening agent within a

limited time. Was a test of that kind of any use in this case? Lime from water-softening was an obvious possible source for agricultural purposes, and he asked whether it was at all the practice in the county to utilise the solid product of such plants for application to the land. He thought not. With reference to carbide waste, the acetylene given off by direct treatment with water was impure, and one would be afraid of impregnating the soil with poisonous gases; he wondered how far that was so.

Mr. F. W. RICHARDSON asked what occurred with regard to the organic acids in the soil, and as to whether the additional lime influenced the fertility of the soil through some action on the bacteria. Did the lime destroy protozoa, and thus particularly affect the development of the necessary microbes?

Mr. B. A. BURRELL remarked that many farmers did not appreciate what an unstable substance lime was, and often stored it in open sheds or exposed to the weather. He had analysed a large number of samples of ground lime. Some contained over 75% of caustic lime; in other samples which had been badly stored the quicklime was as low as 4 or 5%, the remainder being carbonate or hydroxide. Some, however, had been imperfectly burnt. As a corrector of "sourness" this did not matter, but he thought as a rule farmers used it as a soil fumigant and as an agent for liberating reserve plant food—potash and nitrogen. Owing to the quantity of sulphuric acid which was present in the air of our large towns and in the immediate vicinity, and which was mainly deposited on the land by means of rain, most of such land was "sour." At the present time lime either in lumps or ground was difficult to procure, and he had been recommending the application of basic slag at the rate of 5 cwt. per acre; when applied in the late autumn the results had in many cases been excellent. This substance when freshly prepared contained from 2–10% caustic lime, and even when long prepared had an alkalinity equivalent to about 1/10th of its weight of lime. It thus acted as a soil fumigant, a corrector of "sourness," and at the same time yielded the fertilising phosphates.

Mr. H. G. BENNETT thought that arsenical tannery waste was a good deal less common than it used to be, because certain old methods were disappearing from the tanneries. Was there any way of getting over the stickiness of the waste?

Dr. L. G. PAUL asked if there would be likely to be ill effects from the use of waste carbonate of lime from the re-causticising of caustic soda used in the process of washing crude coal-tar naphtha and similar products. These products would contain phenol, cresol, naphthalene, etc.

Mr. H. W. WATSON remarked that he had tried the use of material containing phenols, etc., as a weed-killer. It acted temporarily, but after a while weeds grew as strongly as ever, so that it would appear as if the destructive elements were neutralised or washed out by the rain.

Mr. C. P. FRY asked if waste lime from ammonia stills was likely to be of use. Much of it left the stills unchanged, though the bulk was in the form of carbonate contaminated with varying amounts of sulphides, thiocyanates, etc. He had had a quantity of sludge removed from settling ponds which had accumulated over a number of years, and had found amongst it traces of nitrates such as one would not expect to find in the liquor as it left the stills. Was it possible for a nitrifying organism to work in such a sludge and convert the ammonia present into nitrates, and might the waste be of use on the land, either in the fresh state or after being kept for some years? With regard to the effects on the soil of acid in the atmosphere he had personal experience that the

complaints by farmers of damage caused by smoke were not always justified, the failure of crops being attributable to other causes. The rainfall samples taken in the neighbourhood of a particular colliery were almost uniformly alkaline. The colliery possessed a by-product coking plant, and the waste liquor from the stills was evaporated. Presumably the small amount of ammonia found in this liquor was sufficient to neutralise any acid in the atmosphere.

Mr. W. McD. MACKAY said he presumed Dr. Hanley would not be against the use of lime from water-softening plants, but a difficulty was that it was in a sludgy condition. At present the residual carbonate of lime was usually run into a pit, but if it could be dried it would be in perfect condition for distribution on the land.

Mr. W. LOWSON asked how long an interval there should be between applying dressings of lime and manure. Would it be advantageous to apply manure in the early winter, and lime shortly before planting? How long did it take the ammonia in the manure to become converted into nitrites and nitrates?

Dr. HANLEY, in reply, said that the effects of liming the soil were chemical, physical, and biological, and recent work had shown that liming on some soils promoted the development and activity of bacteria, *e.g.*, azotobacter, to a very considerable extent. Further, Hutchinson and MacLennan had obtained results with quicklime exactly similar to those obtained when a soil was partially sterilised by means of heat or antiseptics. Gas lime usually contained a number of incompletely oxidised compounds and should be applied early. It should be spread out on the surface of the soil, before digging in, for at least three months. No harm would then result. It was a fact that arsenic sulphide was rapidly disappearing from tannery waste, because only a few old-fashioned firms now adhered to old methods. Sodium sulphide and calcium chloride were not harmful if sufficient time elapsed for the oxidation of the sulphide before a crop was sown. Sodium chloride was toxic if present in excessive quantities, but there would not be sufficient present in such waste lime for an ordinary dressing to produce toxic effects. With regard to the relative costs of grinding and burning limestone, he had no doubt that any comparison would be in favour of grinding, and he rather thought therefore with Prof. Cobb that ground limestone would be produced to a greater extent as the cost of power became less. It still remained, however, to make it generally realised by farmers that ground limestone was as good as quicklime. In mixing of lime and sulphate of ammonia there was certainly an escape of ammonia, but if they were applied separately and mixed in the soil he should say there was no loss of ammonia; if mixed before applying there would be a loss. As to laboratory tests for effectiveness of lime used for water-softening, so far as he knew such tests had not been applied to lime used for agricultural purposes. In regard to the use of carbide waste, he might say that from samples he had had there was some evolution of acetylene when dilute acid was used, but there could not be very much from the use of the waste product on the soil. Experiments were being made at Garforth now. The value of the grinding of lime depended of course on the better distribution obtained. The relative values for the first year were stated to be something like twelve to one. Five cwt. of ground lime could be applied mechanically—that was with thorough distribution—whereas good distribution could not be obtained with less than 2 or 3 tons if applied with a shovel; but there had to be taken into account the ultimate effects of the

heavier dressing of lump lime in subsequent years. The small amount of lime in basic slag was apparently quite useless for correcting "sourness" in bad cases. It was very often advised for certain soils, but he had known cases in which it had not acted at all until the soil had been limed. It required heavy liming to get over the "sourness"; then the phosphate would act, and until then no addition of essential plant foods would make any difference. Naphthalene or phenolic substances were used for partial sterilisation; substances effective for that purpose destroyed the fauna, *i.e.*, the protozoa, but the spores of bacteria were probably retained in the living state and ultimately became active. The one essential in relation to the use of any waste product containing naphthalene or phenolic bodies was that the injurious effects must disappear before the cultivated crop was put on; otherwise they had the same effect on the crop as on the bacteria and protozoa of the soil. Calcium sulphate was of course of no use to get rid of sourness: it had been used with benefit in the case of alkali soils in America. As to the use of waste lime from ammonia stills, if the incorporated compounds were easily oxidisable they would become harmless after a winter's exposure. He would hardly expect that nitrating organisms would be able to work in a lime sludge of the kind spoken of by Mr. Finn—the presence of cyanides, etc., would make it very doubtful. The recovery quantitatively of the fertilising elements put on to the land in various forms was not accomplished in practice, *e.g.*, in the case of nitrogen approximately 70% of the nitrogen applied in heavy annual dressings of dung may be unaccounted for in soil, crop, or drainage water, and it was assumed to be lost as gaseous nitrogen into the atmosphere.

Communication.

FULMINATE OF MERCURY.

Prof. W. R. HODGKINSON has contributed the following remarks on the paper by G. S. Heaven on "Fulminate of Mercury" (this J., 1918, 143 r):—

In regard to the constitutional formula of mercury fulminate, a formula based on the mode of formation is just as likely to represent the true constitution as one based on the decomposition products. Mercury fulminate cannot be made without the action of nitrous acid, or the red oxides, on alcohol in the presence of the mercury salt. The interaction of pure mercury nitrate solution and alcohol does not give fulminate hot or cold, but a solution of mercury nitrate, to which alcohol has been added, treated with the red gases or a strong solution of nitrous acid, gives the fulminate, the reaction assuming the character of the usual method of making.

The action of nitrous acid, or N_2O_3 , on alcohol may be expressed by

and this "fulminic" acid in presence of a mercury or silver salt forms an insoluble compound which separates from the sphere of action. Certainly nitric acid is re-formed during the precipitation of the fulminate. When fulminate is boiled with water for some time a moderate yield of mercury cyanate is obtained, especially if the mixture is well agitated during the boiling.

As to the poisonous properties of fulminate the writer of this note has certainly suffered from its effects, for although a heavy substance it "dusts" very readily when in a dry state.

April 24th 1918.

PROF. HENRY LOUIS IN THE CHAIR.

THE CONSTITUTION AND INFLUENCE OF A CORED DENDRITIC STRUCTURE IN ALLOYS.

BY O. SMALLEY.

The data available on the constitution and influence of the cored dendritic structure in alloys was sparse, and had hitherto received but little attention from either the ferrous or non-ferrous metallurgist. To the former, its presence is most common in low-carbon-nickel steels, in all grades of nickel-chrome steels, and in common steels which have either been scorched during melting or incompletely de-oxidised. It may or may not be detrimental in its influence, various opinions prevailing as to its significance; it is seldom regarded with disfavour. This may be due to its almost innate connection with all commercial steels and to its persistency irrespective of subsequent treatment, mechanical or thermal, also to it being in no way associated with the carbide the physical condition and geometrical form of which are primarily responsible for the ultimate value of all steels.

To the non-ferrous metallurgist a dendritic structure indicates poor physical properties. Its presence can nearly always be accounted for and in general is due to non-homogeneity of the constituents. In such cases its removal is purely a question of subsequent heat-treatment to effect diffusion. Failing this, combined mechanical and thermal treatment is always effectual except in some special alloys where its origin is similar to that in steel; in these cases its presence persists after repeated rolling and annealing.

An example of this type is found in oxygenated nickel silver, and Thompson¹ states that "nickel silver exhibiting this structure is almost devoid of ductility, although the crystal grain be of normal size."

In view of these facts, before considering the actual influence of this structure on the commoner alloys, it is necessary first to consider the genesis of the structure, and to review briefly our present knowledge of the relation of composition and structure to the physical properties of metals and alloys.

Genesis of micro-structure.

In all alloys the micro-structure has its origin in the freezing-out from the molten state, hence for the purpose of this investigation metals and alloys will be subdivided into two classes:—I. Pure metals and those alloys which freeze at one specific temperature; II. Alloys which freeze through a range of temperatures. This classification enables a clear conception to be framed as to the nature of the physical changes that accompany alloys during solidification, and it also shows at a glance whether an alloy may, or may not, be subject to the influence of a cored dendritic structure.

The origin of each crystal grain of alloys of class I. is its centre, from whence it develops in a regular fashion determined by the crystallographic system to which it belongs; the last particle of

metal to freeze is at the same temperature as the first particle, so that each crystal grain in such alloys is homogeneous throughout.

Where an alloy freezes through a range of temperatures, a different type of crystal growth results, and it is characteristic of solid solution crystal grains of an isomorphous mixture of metals to develop faster in one direction than in another, resulting in the formation of unbalanced crystallites. This is illustrated by photomicrograph No. 20, which shows the formation of the primary and secondary axes on incipient solidification and the subsequent emanation of other axes, which take a higher order of symmetry; these continually grow into, and are fed by the residual or mother liquor until solidification is complete. In the alloy cited, which crystallises in the cubic system, these skeletal arms are shown to have developed along the principal axes of the cube. Such a structure at once indicates that sufficient time has not been allowed during solidification for the adjustment of the homogeneity which theory demands, so the intensity of the heterogeneity or, as it is more commonly known, "coring" of each crystal grain of alloys in this class will be dependent upon the alloying properties of the metals concerned, the range of temperatures through which the alloy freezes, and the rate of cooling during solidification.

The relation of composition and structure to the physical properties.

Theoretically the physical properties of all metals and alloys are governed by their composition and structure. Unfortunately practice does not always conform to theory, and many external influences

FIG. 1.

must be taken into consideration, *viz.*, occluded gases, volume changes on solidification, temperature, impurities, and other external agencies, each modifying theory to a degree totally dependent upon the constitution and nature of the metal or alloy. This is augmented in those metals and alloys which undergo allotropic and isomeric changes respectively, and in many instances by physical changes which are not accompanied by any apparent structural alteration. An example of this type is found in the immediate softening and subsequent hardening of aluminium and aluminium alloys containing small quantities of magnesium, when quenched in water from a temperature between 400° C. and 500° C.

It is, then, clear at the outset this investigation is limited to those alloys of which we have a more precise knowledge.

CLASS I. ALLOYS.

Of the alloys in this class are those of eutectic composition, intermetallic compounds, and some special alloys having an exceedingly small freezing range, e.g., aluminium-bronzes and high-tenacity brasses.

Of these only high-tenacity brasses will be considered, and only for the purpose of bringing out clearly the influence of a cored dendritic structure in alloys of class II.; and to show that, given an isomorphic alloy of homogeneous texture, strength and ductility depend upon the size, orientation, and external form of the crystal grains, so that if suitably cast, neither mechanical nor thermal treatment is beneficial.

Full data concerning the treatment and test results obtained in practice of two such alloys are included in Table I. These figures call for no special comment, being self-explanatory. The microstructure of each alloy is similar, with the exception of the size of the crystal grains, and is illustrated by fig. 1.

The former was made to the following composition:—Cu 94, Sn 5, P 1%. Twelve bars were chill-cast in pairs 9 in. × 1½ in. × 1½ in. from the same melt at varying temperatures, ranging from 1112° C. to 1040° C. The temperature was measured by means of a platinum-platinum rhodium thermocouple protected by a fused silica sheath. The charge was well stirred before reaching each pre-designed successive temperature, obtained by allowing the metal to cool, after which each successive pair of bars was cast.

Tensile and Brinell hardness tests were made on each bar and are included, together with the casting temperatures, in Table 2.

Microstructures, representing casts 1, 3, and 6 respectively, are illustrated by figs. 2, 3, and 4, at a magnification of 50 times, showing a coarse complex dendritic structure to exist in cast no. 1; a similar structure in cast no. 3, with the exception of the absence of the dendritic pattern; and no. 6 to exhibit an adumbrant cellular structure.

The effect of the dendritic structure is thus

TABLE 2.

Influence of varying casting temperature on the properties of phosphor-bronze castings poured from the same melt.

CLASS II. ALLOYS.

Amongst the alloys examined of this class are tin-bronzes, brasses, light alloys, and steels.

Tin-bronzes. Of the innumerable range of alloys offered by this series of bronzes, two of the most important will be considered, namely, ordinary phosphor-bronze and Admiralty gun metal.

clearly shown. It is, nevertheless, palpable that although casting too hot is detrimental, through permitting the formation of a highly crystalline structure, it is equally detrimental to cast at any temperature below that which just suffices to suppress its formation; the poor physical properties that accompany the low casting temperature are

EFFECT OF HEAT TREATMENT ON ADMIRALTY GUN METAL.

not, however, attributable to structural so much as to mechanical defects, which are manifest in the form of entrapped oxide, liquation spots, and cold cracks due to the increased viscosity of the metal.

It may then be concluded that (1) the presence of a cored dendritic structure is embrittling in its influence on phosphor-bronze; (2) the correct casting temperature depends upon the size and shape of the casting to be made, and for general practice the best results will be obtained between 1100°–1075° C.

Admiralty gun metal. This alloy, while permitting a wider range of casting temperature, is just as susceptible to the formation and the objectionable influence of a dendritic structure.

C. P. Karr and H. S. Rawdon² in an investigation on this alloy found for ordinary sand and chill castings the range of temperature permissible lies between 1120° and 1270° C. This is to some extent supported by our own practice, provided the alloy is subsequently treated to remove the dendritic cores formed at the higher temperatures. Failing this, the best results in the case of chill castings are obtained from 1100° to 1170° C., and in sand castings from 1125° to 1200° C.

That the absence of a dendritic structure is of high importance and of far greater moment than a fine crystal grain may be gleaned from the following experiment:—

Two 25-lb. casts of this alloy were made from 50% virgin metal and 50% previously made alloy, under identical conditions. Two ingots were cast

matrix of a cored solid solution of copper-tin-zinc, in which are embedded in the interstices of the primary skeletal crystallites numerous granules of a hard light-coloured rich-tin compound.

Photomicrographs figs. 6 and 8 show annealing to have almost removed this composite dendritic matrix, there existing now a simple polyhedral crystalline structure—common to that of pure metals—except for the presence of some of the hard copper-tin compound, which is still present, but in reduced quantities.

It is clear from these that had the annealing been such as to effect complete solution of this hard, brittle compound into the now homogeneous α -matrix, better results would have been obtained on test, its presence being conducive to both inter-crystalline and intergranular brittleness.

H. S. Primrose³ states that "for general work, such homogeneity is obtained by annealing this alloy at a temperature of 700° C. for 30 minutes."

J. C. Longbottom and A. Campion⁴ find this temperature to be injurious to Admiralty gun metal castings, and that homogeneity is best obtained by a long annealing at 250° C.

The present experiments, however, indicate that such general statements cannot be made, and experimental work conducted on this class of alloy at different times proves that the treatment necessary to obtain the best results is determined by the size and condition of the copper-tin compound, and in the case of large sand castings its removal is not technically practicable.

TABLE 3.

Effect of heat treatment on the properties² of Admiralty gun metal.

Mode of casting.	Casting temperature, °C.	Subsequent treatment.	Yield point, tons per sq. in.	Maximum stress, tons per sq. in.	Elongation, % on 2 in.	Reduction of area, %	Fracture.	Brinell hardness no.	Number of crystal grains per sq. cm.
Chill ..	1175	None	10.90	11.20	Nil	Nil	Uniform, exhibiting dendritic markings	85	2200
Chill ..	1175	Annealed 725° C. for 45 mins.	9.50	15.30	12.00	11.00	Uniform, granular	55	1760
Sand ..	1175	None.	10.00	14.30	6.00	7.00	Coarse, exhibiting a marked dendritic pattern	78	69
Sand ..	1175	Annealed 725° C. for 45 mins.	7.80	14.20	16.00	26.00	Coarse, presenting an abundant dendritic pattern.	55	70

into chill moulds, and two into dry sand moulds. Casting in each case was performed at a temperature of 1175° C., the metal reaching a maximum temperature of 1270° C. in the furnace. Tensile and Brinell hardness tests were made in duplicate on one of each of the chill and sand cast ingots before and after heat-treatment. The heat-treatment consisted of an annealing at 725° C., during 45 minutes, cooling off in air. The results of the tests are embodied in Table No. 3.

The nature of the structural changes responsible for the improvements in the physical properties wrought by heat-treatment in both the chill and sand cast specimens are shown by figs. 5, 6, 7, and 8, each specimen in the "cast" condition displaying a structure of a complicated nature, the chill cast specimen being somewhat similar to that of the phosphor-bronze previously considered.

Both the sand and the chill cast specimens of this mixture consist of a complex definite dendritic

Brasses. An examination of the constitutional diagram of the copper-zinc series of alloys shows all " α ," and to some extent " $\alpha\beta$ " brasses, to enter into the class of alloys under consideration. The principal value of α -brasses being their malleability and ornamental appearance, the effect of a dendritic structure, although always manifest—due to the high casting temperature necessary—is of little moment. That its presence can be shown to exercise some influence, in spite of the native softness of such brasses, however, is of the greatest importance in its direct correlation to other alloys where combined tenacity and ductility are the essentials. Unfortunately, the investigation could not be conducted by simply modifying the casting temperature, as in the case of the tin-bronze series of alloys, for if cast too hot they are accompanied by numerous defects in the form of blowholes,

oxide contamination, and hot cracks; or if cast too cold, "spilliness," entangled oxide, and foreign matter.

The difficulty was eventually overcome by taking three casts of 70:30 brass made under identical conditions, cast from the same temperature into slabs 4 ft. \times 1 ft. \times 1 in., and having everything in common with the exception of the presence of 0.20% of arsenic added to one, and 1.00% of iron to another. The lower half of each slab was used for the requisite physical tests in the "cast" condition. Similar tests were made from the upper half of each, after the cast cored structure had

(2) Its formation is augmented by those impurities which are soluble in the molten alloy and prevented by those impurities which are insoluble.

$\alpha\beta$ -Brasses. These will only be considered briefly, the short range of temperatures through which they freeze being such as almost to prevent any difference of composition between the first and last portions to solidify. This is particularly interesting because this group of alloys forms the bedrock on which is built all high-tensacity brass, and proves that their physical properties will be purely a question of their polymorphic nature and fineness of the crystal grain.

TABLE 4.

Influence of impurities on the properties of 70:30 brass before and after the removal of the cast structure.

3	69.50	29.50	Nil	1.00	"As cast" Cold-rolled and annealed	10.70 11.00	24.00 26.50	50.00 54.00	59.30 67.00	72 76

been removed and the brass restored to its original hardness. This latter was achieved by cold-rolling to 0.45 inch in five passes, with one intervening anneal and a final anneal, the temperature of which was predetermined by experiment.

The test results are given in Table 4, and show that in each sample the improvement wrought by the removal of the cast structure is different, being a maximum in No. 2 and a minimum in No. 3. The explanation of this is not far to seek. In No. 1, a cored dendritic structure is replaced by a homogeneous one composed of polygonal twin-crystals (compare figs. 9 and 12). In No. 2, a similar change is evinced, but the dendritic structure is more marked in the cast sample (compare figs. 10 and 12). In No. 3, a minimum structural change has resulted (see figs. 11 and 12), the cast sample of this brass being shown to exhibit no trace of a dendritic pattern.

That the added impurities should have such diverse effects on 70:30 brass when cast from the same temperature—in the one case accentuating, and in the other preventing, the formation of a dendritic structure—was to be expected on consideration of their nature, arsenic being soluble in brass when molten, forming an arsenide of zinc and copper; and iron forming an insoluble copper-iron compound.

The influence of the former, then, is analogous to that of phosphorus in steel, which forms a phosphide of iron and is generally responsible for the well-known "ghost" marks or heterogeneity common to ordinary steels; while the latter, which is present in the form of finely disseminated, insoluble particles, forms the nucleus for the germination of the crystal grains, so that on solidification crystal growth now tends to proceed radially from each nucleus, resulting in the gross cored dendritic structure being replaced by a fine grained texture, each grain having an onion-like type of coring, *i. e.*, it is heterogeneous in the form of concentric layers.

It may then be concluded,

(1) A dendritic structure, although of little moment in " α " brasses, is distinctly embrittling.

Light alloys. In the course of recent research on this series of alloys, it has been impossible to correlate structure with physical properties. Moreover, a metallographic study of aluminium and its alloys may be said to have only just begun. In one instance of the manufacture of some small articles from an aluminium-copper-zinc alloy, a great variation was found on tensile test. The microscope showed each sample to be equally sound, but on etching, the brittle castings presented a cored dendritic structure. The test results obtained are given in Table 5. In spite of the evidence of this structure being responsible for these results, they must be accepted with some reserve, there being many physical changes accompanying this class of alloys which are at present little understood.

Steel. The most noteworthy feature of the non-ferrous alloys just considered is that the harder the alloy, the more susceptible is it to the embrittling influence of a cored dendritic structure. It then follows that its absence in steel is of paramount importance, particularly with regard to special steels the principal qualities of which are combined strength and ductility. This is disconcerting, as at the present time the nature and constitution of heterogeneity in steel are conjectural. Its origin cannot be traced directly to either incomplete diffusion of added elements, or to the presence of the commoner impurities; although in every instance it is directly connected with the freezing out of the steel from the molten condition, and is the progenitor of the ghost-markings manifest in all "worked" steel.

FIG. 20.

The conflicting views on ghosts that have been expressed by various authors, notably Arnold,⁵ Stead,⁶ le Chatelier and Lemoine,⁷ Charpy and Bonnerot,⁸ Hatfield,⁹ and Rosenhain and Haughton,¹⁰ show that ghosts in steel are not only little understood, but that they are only indirectly connected with the commoner foreign elements, such as phosphorus, silicon, sulphur, and manganese. The variations found by each of the forementioned investigators when working with the same reagent, or with reagents having similar characteristics, indicate their presence to be attributable to some inherent defect common to all steels in a greater or lesser degree when made by an oxidising process; this defect has not received due consideration, and in consequence each claims to have discovered something new. This is supported by the fact of copper-depositing etching reagents being found to be equally sensitive to oxides, silicates, sulphides, gas fissures, phosphide, and even mechanical defects, and to reveal heterogeneity equally well in high or low grade steels, although the carbide be homogeneous. This is exemplified by figs. 13 to 18. Figs. 13 and 14 were taken from the same section of nickel-chrome steel (C 0.45, P 0.02, S 0.021, Si 0.1, Mn 0.06%) cast from a "wild" heat, and etched with nitric acid and cupric chloride respectively.

Figs. 15 and 16 represent a special high grade nickel steel containing C 0.40, Si 0.06, Mn 0.35, S 0.022, P 0.016, Ni 3.50%, when etched with picric acid and cupric chloride respectively.

Figs. 17 and 18, representing a poor quality carbon steel containing C 0.65, Si 0.12, Mn 1.10, S 0.034, P 0.038%, etc., were etched with the same reagents as those shown in figs. 15 and 16 respectively.

These illustrations show the carbide in each sample to be uniformly distributed and the ghosts to have no relation to the heterogeneity of the essential constituents or to phosphorus, sulphur, manganese, or silicon, although, as fig. 18 indicates, their presence is intensified by such impurities.

Impurities.

In view of the changes which steel undergoes in the process of solidification, impurities will influence it to a degree depending upon their nature and quantity. As regards common steels the elements to be considered which give rise to these impurities are carbon, aluminium, silicon, manganese, sulphur, occluded gases, and phosphorus; and in special steels, similar elements, together with the additional elements which so classify it.

Carbon, as has been shown in the three steels cited as exhibiting ghosts, was homogeneously distributed, so does not call for consideration.

Aluminium, silicon, and manganese may be considered together, each being used as a deoxidant, although their actions are somewhat different. They are used singly and conjointly, but whether they remove the oxygen or render it soluble in the steel as gas or oxide is not known. There is, however, every reason to believe that both silicon and manganese perform the latter function, so are preferable to aluminium so far as the casting qualities of the steel and the production of a sound ingot are concerned, but, it is generally believed, to the detriment of the steel.

Incidentally, both silicon and manganese are also beneficial in removing the injurious influence of sulphur when present as iron sulphide, converting it into a comparatively inert sulphide.

As far as gaseous impurities are concerned, little

can be said. Oxygen has been mentioned, but there still remain to be considered hydrogen, carbon monoxide, and nitrogen. Their extreme solubility in the molten steel is well known, but to what extent they are soluble, in what form, and how they influence the finished product, is unknown.

In common steel, then, we may have

(1) Aluminium present in solid solution or as an insoluble oxide.

(2) Silicon and manganese, in solid solution, as manganese silicate, or as a complex insoluble sulphide.

(3) Phosphorus present in solid solution as Fe₃P.

Relation of impurities to ghosts.

Impurities in steel then are of three types and may be classified as follows: (a) those insoluble in the molten metal; (b) those separating out as definite constituents during solidification; and (c) those entering into solid solution. Hence it is quite evident that the mode of crystallisation of steel from the liquid state cannot be followed so readily as with non-ferrous metals and must depend upon the type of impurity most manifest.

Of the insoluble impurities, sulphides and silicates, being in a viscous condition—their melting point being lower than that of steel—are entrapped in the meshes of the branches of the primary crystallites, where they freeze, taking a skeletal form of the primary dendrites. If present in abnormal amounts, together with entangled slag, free alumina, extraneous refractory material, etc., they will, of course, tend to act as suggested by Arnold.

Whether impurities of class (b)—which separate from solution during solidification—are present or not, will depend upon the condition of the metal in the ladle; if scorched or oxygenated, it is quite conceivable that oxide may be rejected on freezing and be present in the finished steel in mechanical admixture at the junctions of adjacent crystal grains. An example of this type is illustrated by photomicrograph fig. 19. In consequence there is every reason to believe that a steel correctly de-oxidised, so far as the production of a sound ingot is concerned, may still contain a considerable amount of oxygen in solid solution as oxide, the solubility being increased by the presence of such elements as nickel and chromium. If this be so, the influence of this oxide will be similar to those impurities of class (c), which exist in solid solution, and intensify the production of a cored dendritic structure.

The influence of phosphorus in this direction has been shown by Stead (*loc. cit.*), and the fact that an oxygenated steel free from phosphorus, silicon, manganese, or the other common impurities, exhibits an exactly similar effect, points to the presence of such dissolved oxide which, due to the mode of crystallising of the steel from the liquid state, is concentrated in the interstices of the primary crystallites.

The relative positions occupied by impurities in steel must then depend upon numerous factors; if a common grade steel containing both soluble and insoluble impurities, cast from the correct temperature, they will be contained in and between contiguous crystal grains; if the insoluble impurities be in excess, then the soluble impurities will be more concentrated in the external zones of each crystal grain. If the soluble impurities be predominant, the insoluble impurities will be forced between the primary skeletal arms and subsequently solidify, *in situ*, together with the residual material containing the bulk of the soluble impurities.

In special steel containing soluble impurities, the extent of coring will depend upon the quantity of the impurities present, together with alloying properties of the added element or elements.

Influence of a cored dendritic structure on the physical properties of steel.

An ingot of nickel chrome steel of the composition C 0.50, Si 0.10, Mn 0.07, S 0.025, P 0.03, Ni 2.00, Cr 2.00%, was used for this investigation; it was known to have been cast too hot, and found to have a marked dendritic structure.

Static and dynamic stress tests were taken from one half of the base of the ingot, in the "cast" condition, after annealing, and after hardening. Similar tests were made from the other half in the annealed and hardened conditions, after reducing by "forging" to one half the original cross sectional area and also after reducing to one-eleventh the original cross sectional area.

perature of 18° C., and subsequently tempered in oil at 165° C., for 1 hour. This latter treatment was performed as a safeguard against cracking on grinding. The test results are detailed in Table 6, and clearly show the improvement effected by "forging" on this steel, in both the annealed and hardened condition.

The structural changes responsible for this improvement are depicted by photomicrographs figs. 20, 21, and 22, representing samples nos. 1, 1F, and 1FF respectively. In either the annealed or hardened condition, delineating the progressive deformation of the primary dendrites by mechanical treatment.

That neither fineness of the crystal grain nor homogeneity of the carbides has any influence is

TABLE 6.

Effect of forging on the physical properties of nickel chrome steel in the annealed and hardened condition.

1FF.	"As forged," reduced to 1/11th the original cross sectional area.	Annealed 900° C. 1 hr. Cooled in furnace. Reannealed 790° C. 1 hr. Cooled in furnace.	30.00	49.60	26.00	63.00	Grey velvety. Cup and cone.	207	51	201	72
	"As forged," reduced to 1/11th the original cross sectional area.	Annealed as above and oil-hardened.	124.00	124.00	1.00	Nil.	Fine, amorphous.	578	140	7	2½

Forging was performed at 1650° C., one heating sufficing for the former reduction, and two heatings for the latter. Each sample was given a double anneal, performed at 900° C. and at 790° C., under identical conditions. The efficacy of this treatment is made apparent by the similarity of the tenacity and hardness figures obtained from each sample, the former being 50 tons per sq. in., the latter 207.

The remaining portions from each of the annealed samples were machined to the same dimensions for hardening purposes, 0.01 in. being allowed for removal by grinding after quenching.

Each sample was heated, in an electric tube furnace, to a temperature of 80° C. ± 2° C., above the calescence point, quenched in oil having a tem-

perature of 18° C., and subsequently tempered in oil at 165° C., for 1 hour. This latter treatment was performed as a safeguard against cracking on grinding. The test results are detailed in Table 6, and clearly show the improvement effected by "forging" on this steel, in both the annealed and hardened condition.

It may then conclusively be stated that "cored" dendrites present in nickel chrome steel give rise to cleavage brittleness, and that "forging," although not affecting diffusion, causes an interpenetration of the branches, and if carried far enough removes its embrittling propensities, tending to give to the steel a fibre, thereby strengthening it against impact shock applied at right-angles to the direction taken by it, but weakening it if applied in a parallel direction.

This latter is substantiated by single blow impact tests which were made on longitudinal and transverse test-pieces cut from each annealed sample, the results of which are given below:—

Impact figures in ft.-lb.

		Longitudinal.	Transverse.
1A	..	26	24
1FA	53	37
1FFA	72	26

Possibly the most striking feature of these results is the considerable improvement effected by forging in the reduction of area and the shock-resisting properties when in the annealed condition. The greatest influence of the removal of the dendritic structure, however, seems to be when the steel is hardened, and although samples 1 and 1FF have everything in common with the exception of the crystalline formation of the primary coes, these show a difference in the tensile tests of 70 tons per sq. in.

Conclusions.

(1) Analogies exist between alloys with regard to the origin, constitution, and objectionable influence of a cored dendritic structure.

(2) Soluble impurities give rise in all alloys to a cored structure which is peculiarly persistent and detrimental to their physical strength, despite subsequent treatment.

FIG. 21.

(3) The geometrical relationship between a cored structure and the crystallographic system to which the alloy belongs is determined by the nature of the alloy, the casting temperature and rate of cooling, and the impurities present.

(4) Ghosts are universal in all steels made by an "oxidising process." They may exist in the absence of solid foreign matter, but the converse does not hold.

(5) Ghosts are an effect of soluble impurities, and the laminated form usually exhibited by "worked" steel is a result of the attenuation of the cored primary crystallites. They are unaffected by any kind of heat-treatment, normal or abnormal; in consequence, if the original dimension of the primary crystallites be known, the degree of mechanical work applied to steel is readily revealed by the aid of a copper-depositing etching reagent.

(6) Many structural anomalies exist in steel, and the copper-depositing reagent is a valuable adjunct to the metallographer if skillfully used.

In closing, I wish to thank Colonel Hadcock for permission to draw upon the data accumulated in the laboratory of Messrs. Sir W. G. Armstrong, Whitworth & Co., Ltd., and to recognise the valu-

able assistance rendered by Mr. R. L. G. Johnston and Mr. R. N. Richardson in the preparation of this paper.

DISCUSSION.

Prof. LOUIS stated that Mr. Smalley had tackled one of the most difficult and most complicated subjects in the range of metallurgy and one on which very many and very widely-divergent opinions were held. It would be difficult to select a better subject for discussion.

Mr. H. DUNFORD SMITH said that some of the figures for maximum stresses given for Admiralty gun metal and for phosphor bronze castings were so very much below what one usually obtained in practice that it made one think there might be some cause for such low figures. He wondered whether some oxide had been occluded in the Admiralty gun metal.

Mr. G. DUNCAN asked how the samples were taken for the estimation of phosphorus and manganese in steel. In making a eutectic mixture of antimony and lead, he had found trouble due to segregation. When a small bar was cast into a small thin mould, there were very marked differences when the sample was sawn through the centre or diagonally.

Professor HENRY LOUIS remarked that dendritic crystallisation was not confined to metals. For a

FIG. 22.

long time he had looked upon dendritic structure in an alloy as an indication of crystallisation through a rapidly-passing phase. He meant that, if one took a homogeneous substance, there was no reason why the crystals should not be perfectly complete. There was sufficient matter to fill out the skeleton, so to speak, of the crystal. In crystallising material like brass, as any one of the particular brasses fell out of solution, the remainder necessarily changed position rapidly and, therefore, it was necessary to suppose that there would not be sufficient material to fill out the skeleton. Up to a point, that appeared to be a feasible explanation, but there was the consideration that the best dendrite that he knew was, probably, the crystallisation on the surface of star antimony, which was usually looked upon as an indication of a very high degree of purity. Obviously, therefore, there must be more than one reason for the formation of a dendritic crystal.

Mr. A. SMOOT said that commercially pure antimony was not absolutely pure; it was very seldom over 99½% of purity, so that there might be enough impurity to help the crystallisation in dendritic form. A cast block of lead when etched gave an appearance very similar to some of the structures

which had been shown in the photomicrographs.

Mr. GRATTON said that most of the ghosts the author had shown were etched with copper reagent. There were other kinds of ghosts that did not require such treatment to show them up, in the cast condition at any rate—ghosts that had got occlusions in the metal. It was evident that there were two kinds of ghosts. Mr. Smalley, with the copper reagent, had shown ghosts on several kinds of steel but, in the ordinary course of events, the speaker did not think it would be fair to refer to these steels as being ghost-marked. It seemed necessary to distinguish between ghost-marks that did harm and ghost-marks that did not. Ghost-marks with occlusions certainly did harm and they were absolutely attributable to the steel-maker. Mr. Smalley had referred to scorching and oxidation but did not exactly indicate whether these were the same. It was the speaker's experience that the hotter the steel was made, within reason, suitable after-treatment, teeming, checking down, etc., was much more likely to get rid of what were known as ghost-marks with occlusions.

Mr. DUNFORD SMITH asked how the "A" sample was modified in Table 1.

Mr. SMALLEY replied that, as to the low figures for the phosphor bronze, the tests he had included were quite normal. They were good, sound works' practice results. The bronze was not entirely free from occluded slag; no metal was. As far as the Admiralty gun metal was concerned, his low results were obtained purposely. The bars were cast in vertical chills $1\frac{1}{2}$ in. square. They were doing some experiments at the time on extruded metal, and bars cast in that way gave information with regard to that point besides showing exactly the influence of the dendritic structure. Dendritic structure was an unbalanced structure and crystals emanating from the plane of the cooling surface which were responsible for the low results in the Admiralty gun metal clearly explained the results to which Mr. Smith had referred and were not due to any untrapped oxide or deleterious slag. As to Table 1 "A" modified, the analysis of cast "A" was copper 59, zinc 38, aluminium 3%. Cast "A" modified was the same alloy except that 1% of zinc was replaced by 1% of iron, the latter being introduced to create a nucleus action for the growth of the crystal grain. In sampling phosphor bronze and the Admiralty gun metal, drillings were taken near the top and bottom of the ingot. In steel, duplicate drillings were taken in different portions of the ingot. The most difficult point with which they had to contend was what the strength of the metal was due to. That was a question to which he could not attempt to reply at present. As to Mr. Gratton's remarks, what he inferred was that true ghosts in steel resulted from soluble impurities, and not from insoluble impurities. Such ghosts were equally detrimental to those produced by insoluble impurities. Insoluble impurities were always present in ghosts in virtue of the mode of solidification of the steel. The insoluble impurity, or the slag to which Mr. Gratton referred, always accompanied ghosts. As regarded the soluble impurity or true ghosts not being detrimental, he thought the tests he had shown completely settled the point that they were actually detrimental, sufficient to cause serious trouble to steel in the absence of any occluded slag. Tests made with the grain and against the grain of the ghosts gave figures, respectively, of 72 tons and 26 tons. He had not really been testing whether an insoluble ghost or an insoluble slag was detrimental or more detrimental than the other ghost. He was trying to demonstrate that a dendritic structure gave rise to ghosts, which were exceedingly detrimental to the quality of the steel.

New York Section.

Meeting held at the Chemists' Club on April 12th, 1918.

PLANNING A RESEARCH LABORATORY FOR AN INDUSTRY.

BY DR. C. E. K. MEES.

(Abstract.)

For the internal organisation of an industrial research laboratory there are two forms of organisation possible. For brevity these may be spoken of as the "departmental" system and the "cell" system. In the departmental system the organisation is that familiar to most businesses. The work of the laboratory is classified into several departments—physics, chemistry, engineering, and so on, according to the number necessary to cover the field, and each of these departments is in charge of a man of suitable scientific attainments. In a large department each of these men will in turn have assistants responsible for sections of the department, all the heads of departments finally being responsible to the director of the laboratory. Under the alternative or cell system the laboratory consists of a number of investigators of approximately equal standing in the laboratory, each of them responsible only to the director, and each of them engaged upon some specific research. Each such investigator, of course, may be provided with assistants as may be necessary.

In practice, some combination of these two systems of organisation is essential and will develop in any laboratory. The form of organisation which is the easiest in administration is undoubtedly some modification of the departmental system, since only by this means can young students, fresh from college, acquire adequate training and at the same time keep in touch with different branches of their subject and avoid the danger of over-specialisation too early. A laboratory should therefore be organised in departments with an intra-departmental arrangement under which a young man who develops the ability to carry out his own work may be able to take up work on his own initiative, still retaining his position in the department and carrying on his work under the general supervision of the chief of his department.

The laboratory itself should be housed in a convenient, special building. It is very advisable that all research work under the same general direction should be conducted under the same roof, although in technical research, where it is often necessary to instal model plants on a small scale, this cannot always be carried out. The annual cost of research work is very high in comparison with the cost of the building itself. The greater part of that expenditure is on salaries, and any inconveniences or disadvantages which may be caused by the working conditions and surroundings can easily depress the production to an extent which renders economies in building very unprofitable. The cost of the research man, in fact, is so high that it is worth while to provide him with the very best facilities for carrying out his work.

Research laboratories are almost always too small, and it is desirable that, in designing such a laboratory, some system of construction should be chosen in which expansion can be obtained by the duplication of units. It is important, also, in designing a laboratory to arrange, if possible, that expansion may take place without any considerable rearrangement.

Everything that has been said as to the necessity for the provision of a satisfactory building applies also to the question of equipment, but with even

greater force. It is an economic error to allow expensive men to be short of the apparatus which they require for their work. The total cost of equipment for a physical laboratory represents about two months' cost of operation, and, if economies are to be made, it is clear they should be made in limiting the amount of work undertaken and the consequent cost of operation, rather than in depriving the employed workers of the necessary tools for their work.

From various sources of published information, as well as from personal experience, it is possible to form an estimate of the cost of a research laboratory per scientific worker employed, taking the term "scientific worker" to cover all graduate men working in the laboratory. It might seem that there would be very great variation in the cost, but in laboratories of the physical and chemical type there is a surprising agreement between the different figures, which show that cost of building and equipment for a laboratory will be between \$3000 and \$4000 per man; it may be taken, therefore, that the first cost of a laboratory will be about \$3500 per scientific worker employed. The annual cost of maintenance of such a research laboratory appears to be slightly lower than the first cost. Probably \$3300 per man would be a fair estimate of the cost of maintenance, and of this about 60% represents salaries and wages and the other 40% all other expenses.

The work of an industrial research laboratory may be classified in three divisions:—

A. Work undertaken on the initiative of manufacturing divisions for the improvement of operations, for the lowering of cost, or in order to locate manufacturing difficulties.

B. Work undertaken with a view to the development of new materials or of entire new processes. This may be initiated by the management, by manufacturing sections, by sales divisions, or by the director of the laboratory or his assistants.

C. Work which deals with the fundamental theory of the subject the results of which, if successful, will lay a foundation for the expansion of the industry as a whole, along lines which usually cannot be foreseen when the research work is commenced.

The work classified under Division A is, of course, common to all industrial laboratories, and many research laboratories in connection with manufacturing plants confine themselves almost entirely to problems arising from the manufacturing division.

Class B includes a large portion of the work of industrial research laboratories, and the best known successes of such laboratories are included in this division. A typical example is the development of the drawn wire tungsten filament by the research laboratory of the General Electric Company, a research which, although originating from a general research on the properties of rare metals such as would be classified under Division C, developed into a study of tungsten with the direct purpose of obtaining a satisfactory lamp filament from the metal. Another example is the manufacture of indigo by the Badische Company. Such researches usually have their basis in some fundamental work.

More rarely do research laboratories work on subjects classified under Division C, that is, on the fundamental theory of their subject. Yet those who do, achieve the most conspicuous successes. The work of Prof. Abbe on the theory of the microscope, and, indeed, all the work on applied optics at Jena, come under this heading. The great success of the Zeiss works is directly due to the attention paid by Abbe to the development of the fundamental theories of optics. At the General Electric laboratory at present much attention is

being paid to the emission of electrons from hot bodies, and from this work there have already developed the Coolidge X-ray tube and the Kenotron high-frequency transformer, while the possibilities of application are as yet only just beginning to be realised.

If proper co-ordination exists between the laboratory and the management, work classified under A and B will certainly be reasonably remunerative, although not necessarily so completely so as to pay the dividends on an investment in the research laboratory, which is commonly expected from such an investment. The same may not appear true in the case of Division C, the fundamental work, which in the hypothetical case discussed would represent nearly a third of the total expenditure of the laboratory; nevertheless, it is probable that this section of the work would be likely to prove the most remunerative of all, as exemplified by such work as that done by Prof. Abbe on the geometrical laws which govern the formation of images by lenses; by the various bureaus of standards in research on analytical methods; the study of the relation between inductance and capacity in alternating electrical circuits; work on the photo-electric effect, the diffraction of the X-rays by crystals, or the emission of electrons by hot bodies, etc.

It is often felt that small industries cannot afford to support scientific research, but this argument is exactly as if it were suggested that small industries cannot afford to support advertising. The object of spending money on research, for a small industry at any rate, is not to support the research but to be supported by it, and it is scarcely an exaggeration to say that the smaller a business is, the more important is it that it should make use of scientific research to the greatest extent possible.

A small business is at a disadvantage in comparison with a large one in regard to all its cost charges. In the purchase of raw materials, in manufacturing, and in selling, its cost per unit of output tends to be larger than in the case of big businesses, but, on the other hand, it is at a real advantage in regard to flexibility and enterprise. Any large business must necessarily be cautious and conservative. The amount at stake is so large that the penalty of error is heavy.

Small businesses can therefore make far more use of a research laboratory and get a much bigger percentage return for the expenditure than any big company can hope to do. In the small business, in fact, a research laboratory closely associated with one of the high executive officers should begin to return a profit within a few months of its establishment, whereas in the case of a large company it may be years before a research laboratory can be considered to be financially successful.

The greatest difficulty in the establishment of a research laboratory in a small business is that any research laboratory will depend for its value upon the quality of the men at the head, or, if the laboratory is really small, of the man at the head, and a small business often feels that it cannot afford to pay even one good scientific man. The solution of this in a technical business might be that the research man should also be an officer of the company, so that his cost is borne not only by the scientific work but also by the value of the executive position which he holds. It may be objected that an investigator would not as a rule prove a capable business man, but there seems to be no particular evidence for this common belief, and there are many examples of men trained in science who have proved extremely good administrators. In many cases it will be found that the technical industries are directed by technical men who were themselves directly concerned with development and manufacture rather than with financial or business direction.

PROCEEDINGS OF THE THIRTY-SEVENTH ANNUAL GENERAL MEETING,

Bristol, July 17th to 19th, 1918.

The thirty-seventh annual general meeting of the Society was held at Bristol University on July 17th, Prof. Henry Louis, the President, in the chair.

The Rt. Hon. the LORD MAYOR OF BRISTOL (Alderman Frank Sheppard), in offering the Society a hearty welcome to Bristol, said that the chemical industry was commanding more attention at the present time than it had done during the whole of its history. He remarked that one of the subjects to be discussed was the question of copartnership, and in that connection he believed that if we were to have peace in industry in the future there must be a far closer co-operation between employers and labour generally than there had been in the past. Many efforts had been made recently to establish this kind of understanding. The average working man now had little interest in the particular industry in which he was engaged. Thirty or more years ago the men who were engaged in a trade were craftsmen and had some interest in their trade, but during the years that had passed since then the boys that had grown into men in the industrial world were simply tiny cogs in connection with the very important industries of our country. Some complaint had been made of the lack of knowledge and of the ignorance displayed by working people as a whole, but they must not complain of that ignorance. It was due to somebody who had been seriously at fault not to have noticed the tremendous change that had gone on during the last 20 or 30 years and to have provided something to make up for what the young fellows lost compared with what formerly was the case. A lad left school at 14 years or so and was put straight into a factory where he was engaged in the most minute part of a particular industry; when he became a man he was no better than what used, in the old days, to be considered an unskilled labourer. Those in industry must see that something should be done to give the boys and men more interest in their industry. At the present time there was a great desire on the part of employees for reduction in the number of hours of labour, and the reason was that their work was so monotonous and uninteresting that they had no real love for it. He believed this would be remedied if they could be given some other interest in life than being a mere cog in a machine.

Complaint was sometimes made in regard to all industries that the right men were not put in the right place and that people in industry did not hold high office in the affairs of the country. They must try to find out whether they themselves were not to blame in that respect. If they wished to occupy the positions which many of those in industry ought to, they must adopt democratic methods. Another complaint was that the Government would not use the services of men in industry to the extent they could. It seemed to him that it was necessary to establish an ideal of honesty with regard to trade which would make the country feel it could appeal to representatives of trade and use their services and knowledge in high positions without any of the suspicion that had existed for so long, when a man in a trade who occupied these high positions was suspect.

Sir ISAMBAUD OWEN, Vice-Chancellor of the University of Bristol, said he had great pleasure in bidding the Society a very cordial welcome to the

University of Bristol. They had had but four years in which to endeavour to develop the University before the war overtook them. They had started with the largest conception of what a university should be and what it ought to aim at. They wanted to see a real seat of learning in the West, an assembly of men and women who were exponents of the various branches of learning in their highest and most up-to-date form, branches of learning not merely literary and scientific, not merely theoretical, but practical; not a piece of machinery for coaching young men and women to pass examinations or an apparatus for turning out a specified number of graduates per annum. The universities of the middle ages, far from concerning themselves merely with theoretical and impractical branches of learning, had their eyes constantly fixed upon the practical occupations which were open to learned men, and whereas learned professions in the universities had once numbered three, at the present day they were numbered by the dozen and their tendency was constantly to increase. It was difficult to see what occupations in the future would not be carried on by the help of systematised and exact knowledge, and thereby the scope of our future universities had become enormously enlarged. The practical aims of a university had been constantly kept before them at Bristol since its foundation, and with a university that had been founded and which was largely maintained by local benefactions, they had esteemed it their primary duty to endeavour to assist the leading industries of the district. The members of the Society of Chemical Industry, who were engaged in turning one of the most abstruse and one of the most rapidly advancing of modern sciences to practical purposes, were very heartily welcome at Bristol.

The PRESIDENT, in expressing the thanks of the Society for the very kind welcome that had been extended, said it was one which peculiarly fitted the aims and objects of the Society. The Lord Mayor had given them a civic welcome on behalf of the citizens engaged in the industries of Bristol and the Vice-Chancellor had given them a welcome on behalf of the seat of learning which was disseminating education throughout the same ranks. It was that combination, the application of science to industry, which was the main object of the Society. The fact that a new Section of the Society had been inaugurated recently at Bristol and was already in such a flourishing condition showed very clearly the way in which the efforts of the whole country were tending. Bristol had long been famous as one of the oldest and most enterprising centres of commerce of the United Kingdom. Its entry into the big industrial ranks had been comparatively recent and that movement was also typical of what was taking place throughout the country. Napoleon was not far wrong when he jeered at us as a nation of shopkeepers. We had always had the unhappy habit of putting commerce before industry as though industry could be founded upon commerce instead of commerce upon industry. Commerce could only be flourishing when there was a powerful and energetic industry supplying the goods. In modern times industry without science was unthinkable. It would be difficult to name any industry which

in some sense or other was not based upon some part of the chemical industry. In that respect the Society represented modern industrialism in the widest sense. The Lord Mayor had pointed out very truly how closely industry and education must be connected in the future if we were to maintain our place among the industrial nations of the world. It was one of the objects of the Society to act as the bond of union between scientific education and the industrial applications of science. The double welcome that had been extended to the Society was therefore entirely gratifying to them and they heartily thanked the Lord Mayor and the Vice-Chancellor.

The Lord Mayor then withdrew and the President took the chair.

The minutes of the last Annual General Meeting and of the Special General Meeting on 15th August, 1917, were read and confirmed.

Messrs. C. J. Waterfall and B. D. W. Luff were appointed scrutineers for the ballot for the election of Council and officers for the ensuing year.

REPORT OF COUNCIL.

During the year the Council has held 10 meetings, Accounts Committee 10, Full Publication Committee 3, Executive Sub-Committee 21, Review Sub-Committee 18, Emergency Committee 3, Annual Reports Committee 2, Finance Committee 4, Premises Committee 4, Reconstruction Committee 1, Library Catalogue Committee 1, Joint Abstracts Committee 3, International Catalogue Committee 2, Chemical Bibliographies Committee 2, Patent Bill Committee 3.

The number of Members on the Register is now 4823, as compared with 4429 last year. Since the last Annual Meeting 665 Members have been elected, and the losses have been 208.

The Council regrets to record the deaths of 56 Members (of whom 15 were Original Members), viz.:—A. Allhusen, W. Raymond Baird, Dennis H. Barraclough, Clayton Beadle, D. Bendix, Sir Samuel Boulton, Bart., Harold R. Braid, Caesar R. Brown, Jas. Buchanan, Jas. Burbridge, Alexander M. Chance, Spencer Chapman, Geo. Christison, T. C. Cloud, C. G. Cresswell, Wm. A. Dixon, Sylvain Dreyfus, J. J. Eastick, J. H. Elson, Prof. G. A. Ferguson, H. Forth, I. Frankenburg, R. Le Neve Foster, R. B. Gibbins, Walter H. Giles, Chas. W. Graham, Jos. Hartley, Norman M. Henderson, G. T. Holloway, T. Kenyon, F. W. Lee, T. W. Lovibond, S. Lupton, W. T. Lye, G. E. McCleak, Peter MacEwan, J. G. McIntosh, W. Marsh, John Meikle, John Milne, Percy S. Nelson, Mulgrave D. Penney, Rufus D. Pullar, Prof. Jos. P. Remington, Chas. M. Reubens, A. Gordon Salamon, Dr. Hugo Schweitzer, R. W. Skipp, J. L. Spoor, Walter S. Tait, Edward C. Thompson, Thos. Tyrer, Walter A. Voss, Jas. L. Wade, Wm. J. Ward, Reginald C. Woodcock, G. S. Woolley, John Young.

Mr. Thos. Tyrer was President of the Society from 1895 to 1896, and was Hon. Treasurer from 1908 to the time of his death; Mr. C. G. Cresswell was General Secretary from 1883 to 1916.

The following members of the Society have died on active service:—Dennis H. Barraclough, Roland B. Gibbins, Walter H. Giles, Percy S. Nelson, and Ralph W. Skipp.

Mr. D. Lloyd Howard was appointed Honorary Treasurer in succession to the late Mr. Thomas Tyrer; and Mr. Thomas Fairley, Honorary Secretary of the Yorkshire Section, was elected a Vice-President in room of Mr. Howard.

To the vacancies caused by the retirement of four Vice-Presidents, Dr. E. F. Armstrong, Professor W. R. Hodgkinson, Mr. Robert L. Mond, and Mr. Walter F. Reid have been nominated.

Mr. W. J. A. Butterfield and Mr. E. F. Hooper were elected Ordinary Members of Council in place of Professor H. E. Armstrong resigned, and Mr. R. D. Pullar deceased, respectively.

Four Ordinary Members retire from the Council, and to fill the vacancies thus created 6 nominations have been received; a ballot will therefore be taken.

The following Chairmen of Local Sections retire:—Mr. T. H. Wardleworth (Canada), Mr. James Macleod (Glasgow), Mr. H. Peile (Newcastle), Dr. R. M. Caven (Nottingham), and Professor J. W. Cobb (Yorkshire). The following have been elected to succeed them:—Dr. W. L. Goodwin, Mr. Quintin Moore, Professor P. F. Bedson, Mr. F. H. Carr, and Mr. W. McD. Mackey.

The following changes have taken place among the Honorary Local Secretaries:—Mr. T. D. Morson (London) and Mr. E. F. Hooper (Newcastle) resigned, have been succeeded by Dr. S. Miall and Mr. H. Dunford Smith respectively. The Council desires to express its thanks to the retiring officers for their services to the Society.

The Council has appointed a Finance Committee, of which Dr. Carpenter is the Chairman, to supersede the Accounts Committee now discharged, having executive powers in all financial matters not involving questions of principle, the decisions of the Committee to be reported to the Council.

Two new Sections have been formed, and are now in full working order:—the Bristol and West of England Section, and the Canadian-Pacific Section (originally called the British Columbia Section). The Council has had much pleasure in accepting the invitation of the Committee of the former Section to hold the Annual General Meeting of the Society this year in Bristol, and it heartily wishes for each of the new Sections a future of prosperity and increasing usefulness.

Owing to difficulties experienced in the way of successfully carrying on its work, the New England Section was dissolved by the unanimous vote of its members. A proposal from the Committee of the New York Section to take over the members of the Section was approved by the Council.

The suggested formation of an Indian Section of the Society was discussed at the Conference of Chemists held at Lahore in January. It was agreed that at present the proposal is impracticable, and that until the number of chemists in India increases or a Government Department is organised the Chemical Science Congress appears to meet all requirements.

There have been two Conferences of Local Chairmen and Secretaries during the year, the first being held in Birmingham at the time of the Annual Meeting and the second in London. These meetings have proved helpful to the officials attending them, enabling them to discuss matters relating to the organisation and development of sectional activities.

The Balance Sheet and Annual Statement of Accounts, which have already appeared in the Journal for 30th June, will be laid before the Meeting.

The Journal for 1917 contained 1290 pages of text, compared with 1274 pages in 1916.

The resolutions unanimously adopted at the last Annual Meeting that (1) the Annual Subscription for Membership of the Society should be raised from 25s. to 30s., commencing on 1st January, 1918, and (2) the life composition fees should be increased by £5 each, were confirmed at a Special General Meeting called for the purpose and held on 15th August, 1917, in accordance with the Society's by-laws.

A Committee has been appointed by the Council to take steps to arrange for a memorial to the late

Mr. Thomas Tyrer, and it has been suggested that such memorial should take the form of a Technological Library to be established in the Society's rooms.

The Council has awarded the Society's Medal this year to Sir James Dewar, F.R.S., in recognition of the conspicuous services which by his research work in both pure and applied science he has rendered to Chemical Industry.

The Council has appointed a Committee to consider the whole subject of the Patent Law and to advise it as to any action that should be taken by it either individually or jointly with other Societies.

In January the Government took over Broadway Chambers, Westminster, and it became necessary for the Council to secure new offices for the Society. Suitable premises were acquired at Central House, Finsbury Square, where ample accommodation is now provided for both the Secretarial and Editorial Staffs.

Subsequently, the Society's printers, Messrs. Vacher & Sons, Ltd., and their total output, were commandeered on behalf of H.M. Stationery Office. The Council has, however, now entered into a contract with Messrs. Spottiswoode, Ballantyne & Co., Ltd., for the printing of the Journal, and the issues from 15th June inclusive have been sent out from their press.

The Council has decided to take into its own hands the publishing and advertising arrangements of the Journal.

In last year's report it was stated that the Council had decided to take advantage of the marked development of interest in the Journal that during the past 2 or 3 years had become manifest, to increase its efficiency and to make it as useful as possible to all those engaged in the various departments of Chemical Industry. The Council is gratified to learn from many sources that its efforts in this direction have not been in vain, and that the new features embodied in the "Review" introduced into the Journal at the beginning of the present year are highly appreciated by the members generally.

At the request of the Association of British Chemical Manufacturers the Council has agreed to allow the "Review" part of the Journal to be the official organ of the Association.

Dr. Charles Carpenter and Mr. W. G. Wagner have been elected members of the Publication Committee.

The Council is gratified with the success that has attended the publication last year of the first volume of its Reports of the Progress of Applied Chemistry. Volume 2 is in the press and will, it is hoped, be published immediately.

In the competition for the Cross and Bevan Prize (with T. P. Latham's Studentship; see Report of Council 1917), four essays were received and examined by Mr. C. F. Cross and Mr. S. S. Napper. These gentlemen reported that two of the essays had sufficient merit to be entitled to a recognition, and they suggested an award from the Prize Fund of 5 guineas to Mr. Edward Wheeler of Bellevue Crescent, Ayr, and of 3 guineas to Dr. H. A. Tempny, Department of Agriculture, Reuniv. Mauritiuis. As there was not sufficient ground for the award of the Studentship, this matter will be re-opened for competition, of which due notice will be given in the Journal.

The Monograph on the "Constitution of Coal" by Dr. Marie C. Stopes and Dr. R. V. Wheeler, based on a joint memoir read in January 1917 before the London Section of the Society, has been published by H.M. Stationery Office on behalf of the Department of Scientific and Industrial Research with the consent of the Council of this Society. The authors were invited by the Chairman of the London

Section to undertake in co-operation the production of a Monograph on the whole subject, which is of considerable importance from both the economic and scientific standpoints and forms a record of work of much value. The Council has purchased a supply of copies of the Monograph, and a copy was sent to each member of the Society with the issue of the Journal for 15th July.

With regard to the Research on Cellulose carried out at the College of Technology, Manchester, at the instance of the Society, Mr. Julius Huebner, under whose direction the work is being done, reports that the results so far obtained are promising, and will form a valuable foundation for more extensive research which he hopes to undertake after the conclusion of the War. The Department of Scientific and Industrial Research has agreed to make a further grant at the rate of £100 per annum from 1st April, 1918, to the end of the academic year towards the expenses of the research.

The Joint Committee of Representatives of the Chemical Society and the Society of Chemical Industry (see Report of Council 1917) have recommended that in order to prevent overlapping in publishing abstracts of scientific papers, the Chemical Society should deal only with papers on pure Chemistry, while the Society of Chemical Industry should restrict its abstracts to those of papers on Applied Chemistry; also that if a sufficient number of members of the one Society who are not members of the other Society desire it, the latter Society should supply them with copies of its abstracts printed in a separate volume. These recommendations have been approved by the Council of each of the Societies; but owing to the small number of applications that have been received for the proposed volume of "Journal" abstracts, the Council has decided not to proceed further with the proposal at present. The matter will be brought up again next year for further consideration.

The Empire Sugar Supply (Technical) Committee which was formed (see Report of Council 1917) in connection with the London Section has now received voluminous and informing replies from the Governors and Secretaries of practically all the Dominions, Colonies, Dependencies, and Protectorates of the Empire, setting forth their production and requirements of sugar for different purposes. A large amount of information has also been obtained regarding the cultivation of sugar beet in this country, and the manufacture of sugar therefrom. The information collected is most valuable, and the work of arranging and collating the statistics is now proceeding.

The following Representatives of the Society have been appointed:—

Sir Boverton Redwood, Bart., and Sir George Bellby, F.R.S., on the Board of Scientific Societies.

Dr. Alfred Holt on the Sub-Committee of the Board of Scientific Societies for considering the future of the International Catalogue of Scientific Literature.

Mr. A. R. Ling and Mr. J. W. Macdonald on the Empire Sugar Research Association.

Mr. E. V. Evans on the Committee of the British Science Guild considering the position of the British Dye Industry.

Prof. F. G. Donnan, F.R.S., and Dr. E. F. Armstrong on the General Board of the National Physical Laboratory; and Prof. Donnan on the Executive Committee of the Board.

Mr. W. F. Reid on the Sectional Committee dealing with chemical products in connection with the British Scientific Products Exhibition to be held in July in King's College, London.

Dr. Carpenter and Dr. Keane on the General Committee of the Chemical and Allied Societies.

The General Committee of Chemical and Allied Societies having had under consideration the publication of Chemical Bibliographies in the English language has resolved (1) that it is expedient to publish an English work of reference completely covering scientific and industrial chemistry on lines similar to those of Beilstein, and (2) that this resolution be communicated to the corresponding American Chemical Societies and their co-operation invited. The Council has approved of these resolutions, and is informed that the General Committee is at present considering a scheme for giving effect to them.

The Council notes with pleasure the formation of the Société de Chimie Industrielle, and is gratified to learn that it is to be organised on the same lines as the Society of Chemical Industry. The Council expresses its hope that the formation of the Société will lead to closer co-operation between the chemists of the Allied countries.

Dr. E. F. ARMSTRONG moved the adoption of the report. As a member of Council he said he felt very proud of the large amount of work that the Council had been able to do. Chemistry and the chemical industry, like all other branches of industry and commerce, were passing through a period of flux and change and the Council had had to consider many difficult problems during the year, and he felt they had reason to be proud of the success which had attended their efforts. A great deal of the success of the Council's work this year had been due to the work which Dr. Longstaff, the Secretary, had done. The formation of the Bristol Section was referred to in the report; he hoped this was a good augury for the future and that the Bristol Section would flourish.

Dr. STEPHEN MIALL seconded the adoption of the report and associated himself with all that Dr. Armstrong had said with regard to the formation of the Bristol Section, to which they wished great success and prosperity.

The report was unanimously adopted.

HON. TREASURER'S STATEMENT.

The HON. TREASURER, in submitting the balance sheet (printed in the Journal of June 30, 1918), said the accounts did not call for special comment except that the Society could congratulate itself upon having a fairly normal balance sheet. There was a gratifying increase in the amount of the annual subscriptions, and as the figures applied to last year, the increase was entirely due to increased membership, because the increased subscription had not then begun to bear fruit. The excess of income over expenditure was £556 4s. 7d. Many items of expenditure had increased and in the current year there would be still further increases.

Prof. SCOTT RUDOLF moved the adoption of the accounts and congratulated the Society on being in such a comfortable financial position. They were all very much indebted to the Treasurer and those associated with him for the manner in which they had safely piloted the financial ship during the past year.

Mr. E. WALLS seconded the adoption of the Treasurer's report. He referred to the loss of the Society's late Treasurer, Mr. Tyrer, and expressed the opinion that they had secured in his successor one who would carry on the high ideals which had always been associated with that office. Having regard to the extreme difficulties of the present period, the great progress that had been made by the Society indicated an admirable state of affairs.

The PRESIDENT, in putting the motion to the meeting, called attention to the fact that this was the first appearance of the new Treasurer, who he thought had every reason to be proud of the statement he had been able to put forward.

The balance sheet was then adopted.

AWARD OF THE MEDAL.

The PRESIDENT said it was his high privilege to announce the award of the Medal of the Society to Sir James Dewar, Fullerton Professor of Chemistry at the Royal Institution since 1877 and President of this Society exactly 30 years ago. It was unnecessary to attempt to catalogue the long series of important discoveries of Sir James Dewar in the numerous and varied domains of physical chemistry that he had long made his own. It was sufficient to say that his labours had most worthily carried forward the brilliant record of epoch-making scientific discoveries that formed the main glory of the Royal Institution. Whilst his discoveries had been confined to pure science, the importance of their practical application would not be denied by the veriest utilitarian who had ever drunk his hot coffee on a winter's morning out of a Thermos flask. It could not be too often or too insistently repeated that it was to the scientific discoverer, to the man who worked out scientific truths for their own sake, that industry was indebted for the solution of its most complex problems. True research had been and was perhaps still too little considered in this country; it was true that attempts had been made recently to repair our past neglect by fostering what our authorities were pleased to call "industrial research," but he gravely doubted whether there really was such a thing as industrial research; what did exist and what we as a nation emphatically required was scientific research, applicable of course to the industries, but research conducted by scientific men in a true scientific spirit. It was to work of this kind that Sir James Dewar had dedicated his life and it was inevitable that discoveries such as those which we owed to him should have proved of value in many different industries, and in not a few cases in industries with which their connection at first sight might seem remote. To take but one example:—The scientific work of Sir Humphry Davy, Sir James Dewar's great predecessor, had enabled him to teach the coal miner how to combat the dangers of an atmosphere of fire-damp; the scientific work of Sir James Dewar had led to the production of one of the most effective forms of rescue appliances that enabled the coal miner to penetrate an atmosphere of after-damp, and the practical value of the one and the other of these inventions could hardly be over-estimated. Yet no one would dream of applying either to Davy or to Dewar the title of practical man. Great as had been the value of Sir James Dewar's work in the advancement of pure science, and in its applications to industry, he ventured to think that it was at least equally valuable to us for the lesson that it enforced that the men capable of work of such high scientific order constituted one of the most important of our national assets. Sir James Dewar had expressed his regret at being prevented from coming to Bristol to receive the Medal in person, and at his request he had much pleasure in handing it for transmission to him to Dr. Armstrong, the son who is following so ably in the footsteps of his eminent father, to whom we owed amongst many other things a most profound and illuminating appreciation of the work of Sir James Dewar. He asked Dr. Armstrong to hand the Medal to Sir James Dewar and to express to him the cordial wishes of the Society for his health and welfare, and the sincere hope that he might long continue to give them the benefit of his scientific investigations.

Dr. E. F. ARMSTRONG said that Prof. Dewar had asked him, as the youngest representative of the old school, to receive the Medal on his behalf. The younger men must find in the example of such men as Sir James Dewar a great stimulus to do their best to advance the science and the

cause of the chemical industry. He was sure that the very happy words the President had said were just those which Sir James would appreciate, because he held the view that there was no research worthy of the name which was not scientific research and that it was by pure scientific research alone that advances would be made in the future. He would convey to Sir James Dewar what the President had said.

PRESIDENTIAL ADDRESS.

Prof. HENRY LOUIS then delivered his Presidential Address as follows:—

My first duty is to thank you for the great honour that you have done me in electing me to the Presidential Chair of this important Society. If I confine myself to this simple expression of thanks, believe me that it is not because I am in any measure wanting in gratitude for the honour that this evidence of your confidence has conferred upon me, but merely because other and more important matters claim our attention to-day.

As the report of the Council has shown, the past year has been one of the most eventful in the history of our Society, and one that has caused all your officials an unusual amount of care and anxiety. In the first place we had decided to alter the form and widen the scope of our Journal, in itself no light task. Whilst we were fully engaged on this work we received peremptory orders from the authorities to vacate our old offices and to find for ourselves a new home elsewhere. I willingly admit that this summary ejection was in reality a blessing in disguise; the activities of the Society had long outgrown our old quarters, which were far too small to allow of our work being carried on satisfactorily, and we have been very fortunate in securing offices sufficiently commodious to provide not only for present needs, but for such expansion of the Society's work as we may fairly look forward to for a considerable time to come. Even before we had fairly begun to settle down in our new abode, the Paper Controller threatened to cut down drastically the supplies of paper for our Journal, and almost simultaneously the Government commandeered at short notice the works of the printers who had published it for so many years. I am only too well aware that many of our members have suffered considerable inconvenience through issues of the Journal being delayed, in some cases for many days beyond their due date, and I can only thank the members as a whole for the forbearance that they have shown under the circumstances; but I think that the facts that I have just stated will make it clear that the fault did not lie with the permanent officials of the Society, and that it is rather to be scored to their credit that the Journal has been kept going as well as it has been, and that the delays that have occurred are quite excusable. I will not go so far as to say that all our difficulties have been entirely surmounted, but we are certainly beginning to get things running rather more smoothly, and I have every hope that a few months more will see everything going as steadily as is possible in the critical times through which we are passing. It is gratifying to be able to add that neither these difficulties nor the world's crisis in which we are involved have retarded the steady growth and development of the Society, which we can fairly claim is to-day in a highly flourishing condition.

Great though the honour is of occupying the Presidential Chair of an influential and old-established Society such as this, I must admit that it entails one serious corresponding drawback. I have before me a long line of illustrious predecessors, and I must endeavour to live up to the high standard set by them as far as lies within my

power. Whilst this difficulty is continuously with me, I am necessarily more sensible of my shortcomings at a moment such as this, when it falls to me to submit to you an address on some subject of general interest; not that it is difficult to find such a topic at the present moment, but rather because all the problems of the chemical industry have already been so well and so exhaustively treated from every conceivable standpoint.

It so happens that the supreme crisis in which the nation now finds itself involved has caused us to revise our views on many subjects, and on none perhaps more completely than on the value of chemistry as a national asset. The nation has gone on for generation after generation, cheerfully committing its government to men whose training necessarily resulted in a complete ignorance of and almost a contempt for scientific methods. Fortunately we have always possessed a sufficient number of quiet unobtrusive workers, whose devotion to science for its own sake has succeeded in maintaining the high standard of British science in spite of official neglect, and it is such men as these who have come to their country's assistance in its hour of need; had it been otherwise, our position would indeed have been hopeless. Under the spur of rude necessity has come a sudden awakening, and even the most case-hardened parliamentarian has come to realise how entirely the nation is indebted for its very existence to the applications of science, and above all of chemistry; and many are at last beginning to recognise that this dependence is as complete in the industries of peace as in those of war. With this recognition has come a desperate rush in the attempt to make up for lost time, as though methods of scientific thought could be learnt in a day, and a century's neglect of scientific principles could be atoned for by the creation of miscellaneous committees. The realisation of the vital need to the nation of a large body of thoroughly trained industrial chemists is at any rate all to the good, and it is a hopeful sign that the best methods of equipping such men for their life's work are attracting increasing attention. Fortunately the public interest thus aroused has enabled chemists themselves to attack those problems in a bolder manner than heretofore, under conditions that would have been impossible had they not felt that they are at last sure of a reasonable measure of public support.

One of the questions that have been most prominently before British chemists recently is that of the best means of securing an adequate supply of chemical engineers to maintain and develop the great chemical industries of the country. Many of us realise that our chemical industry may in some respects be said to have been practically stationary during recent years, and in no respect is this fact more noticeable than in the failure to take advantage of modern mechanical methods of handling large bodies of material. In other words, not sufficient has been made of the application of modern engineering methods to chemical industries. The difficulty undoubtedly lies in finding men who are equally conversant with the chemical problems to be solved and the engineering facilities available for their solution, whilst the problem is further complicated by the fact that the constructional materials employed are frequently required to withstand corrosive influences which lie outside the experience of the ordinary engineer. As has been repeatedly pointed out of late, a man is required with special training, who is for convenience sake usually spoken of as a chemical engineer, though I am free to admit that the term is not in all respects a happy one. No doubt the difficulties in meeting this modern demand for a thoroughly trained chemical engineer are considerable. No

chemist would admit that a man can be considered to be a qualified technical chemist unless he had spent a reasonable amount of time in working in an industrial chemical laboratory; on the other hand no engineer would consider that a man had received a true engineering training unless he had put in a reasonable time in working in the shops. It is therefore evident that unless a young man is willing and able to devote an exceptional length of time to his preliminary training he cannot be thoroughly equipped as a chemical engineer, and the result is almost necessarily a compromise. Hitherto work of this kind has perforce been carried out by men who were either only engineers or else only chemists, and I should have considerable difficulty in saying which I have found to be the worse—the average chemist's engineering or the average engineer's chemistry. There have, of course, been numerous and brilliant exceptions, and most of the important problems of chemical engineering have been tackled by men who had naturally special aptitude in both directions, so that there has been really a large amount of first-class chemical engineering work done, though much of it is scattered through various branches of industry not generally included in what we understand by chemical industry in the ordinary acceptance of the term.

It may perhaps be helpful if we devote a short time to a consideration of the nature of the principal operations that a chemical engineer is called upon to conduct. I propose to limit the field by omitting on the one hand such work as falls generally to the ordinary mechanical engineer, such as the consideration of prime movers, the transmission of force, etc., and on the other hand such processes as can scarcely be classed as mechanical operations at all. This leaves for our consideration a series of such operations as comminution, transport of materials, handling of solutions, filtration, thickening or clarifying, etc. I am omitting from this discussion such operations as involve furnace work, evaporation or distillation, because these can hardly be classed as mechanical operations.

Nevertheless it must not be forgotten that mechanical methods have been applied to most of these; anyone who will take the trouble to read through the list of patents taken out, for example, in connection with mechanically worked roasting furnaces cannot but be struck by the immense amount of ingenuity that has been devoted to this one comparatively simple operation. Such furnaces have, it is true, been devised essentially for metallurgical operations, but many of the principles and methods could be applied readily enough to purely chemical practice; in any case a roasting furnace which generates sulphurous gases forms the starting-point of so important a section of chemical industry that the chemical engineer cannot afford to disregard it. In the same way the steel-maker has evolved a number of highly ingenious tilting furnaces and furnace-charging appliances that are well worthy of consideration from the same point of view. By far the largest-scale distilling operation in the world is that of coke-making; the coke oven is the largest retort used for any purpose, and here again it is interesting to note that mechanical methods both of charging and discharging the retorts have been evolved and are in successful daily use. In the same way many interesting mechanical devices for similar purposes are being employed in gas-making. Again, engineers are applying some of the scientific principles of physics to large-scale evaporations, and it is well known that remarkable economies have of late years been achieved by these means.

The operations of comminution cover a very wide range, varying with the hardness of the materials

and the size to which it is required to reduce them. At one end of the scale we have the so-called rock-breakers, reciprocating or gyrating, capable of dealing with huge masses of the hardest rocks. Some of these have been built large enough to take blocks over $1\frac{1}{2}$ yards cube and to break them down at one operation to about 9 inches; such an immense machine requires about 300 h.p. to drive it, and can break no less than 350 tons per hour. Crushing rolls are extensively used for a large number of different products; like the last-named machines they were originally devised for breaking down ores, but their use has been extended to a vast number of different materials. The modern high-speed roll is a very admirable machine, especially advantageous when it is desired to obtain a granular product suitable for percolation. Rolls have been built of very large size, but the general practice now is rarely to exceed 4 ft. in diameter by 2 ft. face, running with a peripheral speed of about 1000 ft. per minute. Such rolls may be taken as crushing on an average about 5 tons per hour, and absorbing some 10 h.p. I need hardly say that figures varying widely either way from the above averages are to be met with in practice. Californian stamp mills, which are simply mechanically worked pestles weighing up to 10 cwt. apiece, have rarely been applied to anything except the crushing of ores of gold and silver, but can be adapted to a wide range of purposes. They are usually arranged to crush to meshes ranging from $1/50$ th to $1/20$ th of an inch, and their capacities may be averaged as from 2 to 10 tons per stamp head per 24 hours. For still coarser crushing the Lake Superior steam stamp, which is in effect a steam hammer arranged for crushing, can render valuable service; it is generally set to stamp to about $\frac{1}{2}$ inch mesh, and one stamp will crush up to about 1000 tons per day. Both these forms of stamping machinery deserve careful consideration whenever it is required to crush any hard material wet, and when an excessively fine product is not demanded; they are strong, simple, efficient, and thoroughly reliable. For still finer crushing, ball mills are extensively used; these have already been employed in various branches of the chemical industry, but, as far as I know, the improved Hardinge conical ball mill, which has a considerably greater capacity than the original cylindrical ball mill, has so far rarely been employed except for crushing ores. For the finest grinding, tube mills, originally devised for grinding cement, are being extensively used, having largely replaced such appliances as edge runners and burr stones on account of their greater capacity, their higher efficiency, and lesser need for attention. For crushing softer materials, disintegrators of various types are used. I believe that these were first devised for crushing coal, but they have found an extensive application in numerous branches of chemical industry on account of their large capacity and general convenience.

In connection with modern crushing appliances, attention should be directed to the development of various automatic feeders, which are capable of very precise regulation so as to deliver to the machine the exact amount of material that it can treat with the maximum of efficiency. It is quite obvious that either over-feeding or under-feeding will bring about a falling off in this respect, more particularly in the case of such machines as stamp mills and ball mills, which consume practically the same amount of power when they are running empty as when they are running at their full capacity. Out of this extensive range of comminuting appliances with their appropriate feeders it is possible to select machines for doing practically any kind of coarse-crushing or fine-grinding, and on almost any desired scale. Many of these

have not yet made their way into ordinary chemical industries, but they are extensively used in the dressing of minerals and allied metallurgical operations, and their use is obviously indicated wherever large quantities of material have to be broken down.

I need say very little about the appliances available for the transport of materials either to or within the works. Aerial ropeways are coming into general use, and their flexibility and wide range of application are universally recognised; telpher lines of various kinds are well known, belt conveyors, scraper conveyors, screw conveyors, shaking conveyors, have all been thoroughly studied and brought to a high state of efficiency. There are few cases in which one or other of these forms cannot be employed with advantage, so that they have in the majority of important works to a great extent supplanted the labourer with his wheelbarrow, although this time-honoured relic of the days of cheap labour is still too much in evidence in many of our chemical works.

I will add nothing more under this head, but may turn to the equally important and perhaps more difficult problem of dealing with liquids in very large quantities. The economical solution of this problem was indispensable for the full development of an important group of processes—namely, wet metallurgical processes or the extraction of metals from their ores in the wet way. Such processes are by no means new; the extraction of copper from mine waters containing it in solution by the so-called cementation process dates back to the Middle Ages, and the well-known Longmaid process, patented in 1849 and applied successfully to Spanish cuprififerous pyrites in 1860, is still in extensive use. For many years silver was extracted from its ores by various wet processes, beginning with the Augustine process devised in 1849 up to the highly efficient Russel process, based upon the solubility of compounds of silver in sodium-copper thiosulphate; these processes have only been abandoned owing to changes in the nature of the ores in the deeper parts of the mines, which have rendered them more suitable to treatment by smelting. The first wet process for the extraction of gold was the chlorination process, which was proposed simultaneously in 1849 by Plattner in Germany and by Percy in this country, and which was greatly developed in the sixties in California. Quite recently wet processes for the extraction of zinc from its ores by solution and electrolytic deposition have been used to some extent in this country, and have apparently been brought into successful operation in the United States and in British Columbia. Whilst wet metallurgical processes have then been employed for a variety of metals, they have until recent times been conducted on a relatively moderate scale, and the plant employed was of quite ordinary dimensions and presented no especial engineering problems. I prefer, therefore, to direct your attention to some of the very large-scale plants that have gradually been developed within recent years. I might cite for example the huge plant for leaching and electrically depositing the copper from copper ores containing only some 2 per cent. of metal, now being put into operation in Chile, and designed to treat 10,000 tons of ore daily. The best examples, however, for my purpose are to be found in the modern forms of the cyanide process of gold extraction, a process which has been in use for about a quarter of a century, and which has developed slowly from quite modest beginnings and has now reached a very high pitch of perfection. The details of this process are not perhaps very familiar to chemical manufacturers in this country, and it may be helpful to consider it briefly as illustrative of this portion of the subject that I am discussing.

The process has mainly been worked out in the Transvaal, though Australasia, the United States, and Mexico have all contributed to the elaboration of certain of the details, and have worked out methods particularly adapted to local ores or local conditions. The magnitude to which it has attained may be gauged from the fact that the Witwatersrand district alone cyanides over 2½ million tons of ore every month, whilst single nults, like that of the City Deep, treat over 60,000 tons per month. The process, of course, varies considerably in its details, but the general Witwatersrand process may be taken as a typical example. The ore is crushed, generally in stamp mills, to about 30-mesh; in many cases the coarser particles in the pulp issuing from the stamp mill are separated in some form of classifier, depending upon the principle that in such a pulp the coarser particles will settle more rapidly than the finer ones, the coarser particles being then ground finer in tube mills; in other cases the whole of the pulp from the stamp mill passes through the tube mills. The pulp thus produced is streamed over amalgamated copper plates to take out all the free, readily amalgamable gold that it contains, and it is at this stage that the cyanide process proper commences. The pulp is led into some form of settler, a large rectangular or circular tank, or perhaps more often a conical tank about 8 ft. in diameter by 10 ft. deep, in which the coarser sands settle to the bottom, whilst the finer slimes overflow and are led to other appliances in which they are collected. These may be large circular tanks up to 35 ft. diameter by 12 ft. deep, in which there revolves slowly a vertical shaft carrying arms to which inclined blades are attached, which force the thickened pulp through a central aperture. Rectangular tanks are also used, one of the best known of which is the Dorr classifier, which is provided with scrapers moving over an inclined bottom, which steadily push up and discharge the settled material. One such machine will handle up to 200 tons (dry weight) per day, the appliance being quite automatic. The sands and the slimes are thus collected separately, and are each cyanided separately, the same treatment not being applicable to both, owing to the fact that liquids will percolate readily through the sands whilst slimes settle down in a practically impervious mass.

The sands are generally run into a collecting vat by means of some arrangement which distributes them evenly and uniformly, a set of rotating spouts known as the Butters distributor being very generally employed. Whilst the tank is filling with sands the surplus water is drawn off, any slimes in it being collected, and when the tank is full the sands are discharged into the leaching vats, which usually stand at a lower level than the collecting tanks. There are various means of discharging the sands, but it is usually done through bottom discharge doors. The percolating vats are practically always circular in plan, and are built either of steel plates or of wooden staves held together by iron hoops. They range up to 60 ft. in diameter by 15 ft. high, capable of holding 600 tons of sands, but as a rule their diameter rarely exceeds 40 ft. The lower part of the tank contains a frame-work of wood over which is secured a filter made of coconut matting covered with canvas, the filter being wedged tight against the sides of the vat. A series of solutions of cyanide are pumped on to the sands and allowed to percolate through them, and after sufficient leaching has taken place the sands are washed in the same way. I need not trouble you with the chemistry of the process, which is quite well known, as I am now only concerned with its mechanical aspect. It may be added that the quantities of solutions dealt with are quite considerable, being rarely less than 1½ tons per ton of sand treated, whilst they

may reach three times this amount. The exhausted sands are discharged in various ways; if the tanks are low down near the ground level, cranes and grabs may be used, but the general plan is to support the tanks on piers high enough to admit of trucks running beneath the former, when discharging is performed by means of doors in the bottom of the vats, connected, of course, to suitable openings through the filters. It need hardly be said that in view of the enormous quantities of material to be handled, mechanical appliances are used as far as possible, and the discharging is often performed by means of the Blaisdell excavator, a form of plough revolving on a vertical spindle that forces all the sands towards a central discharge door. The remaining portion of the process consists in precipitating the gold from the auriferous solution, which is usually done by running it through a series of boxes containing zinc shavings, upon which the gold is deposited, to be subsequently collected.

The percolation process for sands thus presents but little novelty in its mode of execution, the most interesting feature being undoubtedly the huge scale upon which the operations are conducted, far in excess of anything that has ever been attempted in any other chemical process. Witwatersrand alone treats 1,300,000 tons of sands every month. The case is different when we come to the slimes, which demand very different treatment, seeing that they settle so tight as to be practically impervious to water, and are not, therefore, amenable to simple leaching. This fact was for a long time an obstacle to their being treated at all, but gradually the methods now in vogue were evolved. The first successful process was one of agitation with the cyanide solution, followed by settlement of the slimes and decantation of the supernatant liquid, and this method is still in use where very low-grade material has to be treated. The slimes having been suitably thickened in one of the appliances already mentioned, or by being allowed to settle in large tanks 60 ft. in diameter by 20 ft. deep, are transferred into somewhat smaller treatment tanks and a weak cyanide solution is pumped in. The pulp thus formed is agitated either mechanically or by the injection of compressed air. A usual method consists in agitation by means of revolving stirrers and circulation by a centrifugal pump; in some cases circulation without agitation is found to be sufficient. A vat 24 ft. in diameter by 8 ft. deep holds about 25 tons of slimes (dry weight) which require about 100 tons of cyanide solution. After agitation has been continued for a sufficient length of time, the pulp is run off into a settling tank, where the slimes are allowed to settle as completely as possible, and the supernatant solution is drawn off. One or two washes are given in the same way, about 4 tons of wash-water being required to each ton of dry slimes. It can thus readily be seen that the quantities of solutions dealt with attain to an enormous bulk. The method of agitating by means of compressed air appears to have been evolved in Mexico, the so-called Pachuea tank being employed; this is a tall tank 10 to 15 ft. in diameter and 45 to 60 ft. in height, with a conical bottom; it holds up to 100 tons of slimes, and when the cyanide solution has been run in the pulp is agitated by forcing compressed air through a vertical tube in the centre of the tank; several modifications of this appliance are used, and Dorr has devised a tank in which agitation by revolving arms is combined with the use of compressed air.

The defects of this decantation process are sufficiently obvious, as the settled slimes must under any conditions retain a considerable amount of auriferous solution, so that attention was soon

turned to the possibility of employing filtration. The ordinary filter-press presented numerous objections for use on so vast a scale, prominent amongst these being its small capacity, the expense of working it, and the need for employing much manual labour. One form, known as the Dehne press, has been used to some extent; it contains about 50 chambers with plates 40 inches square, and is operated under a pressure of 3 to 7 atmospheres; such a press holds about $4\frac{1}{2}$ tons of slimes, and can be filled and discharged in two hours, giving a capacity of about 54 tons per 24 hours; its main advantage is that it requires only one-quarter as much solution as does the decantation method. The Merrill filter-press presents the improvement that it can be discharged by sluicing out the contents without its being necessary to take the plates apart. Such a press with 90 plates 3 ft. 8 in. by 5 ft. 8 in. can treat 160 tons per 24 hours; it necessitates, however, an ample water supply, 4 or 5 tons of water being required for sluicing out one ton of slimes.

The special conditions attending the cyanidation of slimes have brought about the introduction of entirely new types of filters, some of which have reached a high stage of efficiency. One of the earliest of these was the Moore filter, which is still used a good deal. The principle of this filter consists in employing a number of "leaves," each of which is formed of a rectangular frame about 2 inches deep over either side of which is stretched a filter cloth; the hollow interspace between the two cloth surfaces is connected by pipes to a suction pump. When such a leaf is immersed in the pulp the solution is drawn through the cloth into the interior of the frame and thence into a receiver, whilst a coating of dry slime gradually builds up on either side until a sufficiently thick cake is formed. The leaf with the adhering cakes of slime is then lifted out and lowered into a tank containing wash-water, which is in turn drawn through the cakes of slime until this is sufficiently washed. The leaf is then lifted out and the adhering cakes of slime are thrown off by forcing air or water into the hollow space inside the frame. In practice the leaves are, of course, not operated singly, but in groups of 30 to 45, suspended from an iron frame, which is lifted or lowered by means of a crane. A group of 35 frames, 4 ft. 6 in. by 6 ft. 2 in., having a total filtering surface of 1836 sq. ft., worked with a vacuum of 18 inches of mercury, will deal with 4 tons of dry slime at a time, or about 40 tons per day. The Butters leaf filter is a modification of the same principle, the leaves being made of canvas stretched over a frame-work of iron tubing. These leaves are fixed in a tank which is filled alternately with pulp and with wash-water; when the washing is complete the cakes of slimes are discharged into the tank by water pressure and are generally sluiced out. Such a filter with 80 to 90 leaves, 10 ft. long by 5 ft. deep, takes a charge of 20 to 25 tons at a time, or treats 160 to 200 tons per 24 hours. This is one of the most satisfactory filters yet devised, and is largely used in the Transvaal. Out of one million tons of slime treated monthly on the Witwatersrand, Butters filter installations are now treating over half a million tons, so that this may be looked upon as a thoroughly well-proved appliance. In the Kelly filter, long, relatively narrow leaves are employed, which slide into a slightly inclined cylinder, the latter being about 5 ft. in diameter by 14 ft. long, and carrying 13 leaves, having a total filtering surface of 1200 sq. ft. Filtration is performed under a pressure of about 2 atmospheres; the capacity of such a filter may go up to 100 tons per 24 hours, and the final press-cake may be obtained very dry, retaining in some cases only 10 per cent. of moisture.

A filter used to some extent in Mexico is the Burt filter, which consists also of a horizontal cylinder either revolving or stationary, the cylindrical shell being lined with suitably arranged filter cloths. Slime and wash-water are forced in under a pressure of 2 to 3 atmospheres. Air is then forced in the opposite direction through the filters, thus stripping off the press cake. It is claimed that these pressure appliances work with a very small power consumption, less than required for the more usual suction presses. There is, however, no doubt but that one or other of the various types of leaf filter is by far the most generally employed. I may add that there are a good many other forms in addition to those that I have mentioned.

All the filters so far described share with the ordinary filter-press the drawback of being discontinuous in their operation; there have, however, been several continuously acting filters devised and used successfully. A good example is the Ridgeway filter. This consists of horizontal filtering leaves carried on arms attached to a revolving vertical hollow shaft; they are thus caused to traverse an annular trough divided into three compartments; one contains the slimes to be filtered, another the wash-water, whilst the third receives the exhausted press cake. The filter leaves, which carry a filter cloth on their lower surface only, run on an annular track; the interior of each is connected by pipes to a suction pump whilst it traverses the first two compartments. The track is so shaped that each leaf is in turn immersed in the slime tank until a sufficient thickness of slime cake has been formed, then rises out of it and dips into the next section, where wash-water is drawn through it, rises out of this again, and finally passes over the third compartment, where the slime cake is forced off by compressed air, after which it again enters the slime compartment, the operation thus being continuous. There are usually 12 arms, each carrying a leaf with a filtering area of 4 sq. ft.; the total power required is about 5 h.p., and the capacity is up to about 65 tons per 24 hours. This filter is quite extensively employed in West Australia.

The Oliver continuous filter is largely used in the United States of America. It consists of a hollow drum up to 15 ft. in diameter by 20 ft. long, mounted on a horizontal axis. The cylindrical surface forms the filter proper, and it is immersed down to the axis in a tank of slimes, in which it revolves at the rate of 6 to 12 revolutions per hour. As it traverses the slime the solution is sucked through, and a cake of slime forms upon the filter; on emerging from the slime tank the cake is washed by means of a spray, the wash-water being also drawn through the filter. Finally the adhering cake is loosened by forcing compressed air through the filter from the inside, and it is removed by means of a scraper. This machine is capable of treating up to 150 tons of dry slime per 24 hours.

There is no difficulty in dealing even with the enormous volumes of solutions in cyanide plants as long as these are tolerably clear, any ordinary type of pump being quite suitable for the purpose. Special methods have, however, been devised for elevating the thick slime and sand pulp. One such device is the "tailings wheel," built like a water-wheel with the buckets on the inner side of the rim; instead of the falling water rotating the wheel as in a water-wheel, the rotation of the wheel elevates the pulp; these wheels have been built up to 70 ft. in diameter, have large capacities, and are but little liable to get out of order. Special ram pumps are also used in which the ram is protected from the action of the sand by a film of clear water; another successful type for relatively low lifts is the Frenier spiral sand pump. Of the

ordinary forms of centrifugal and other pumps and air lifts there is no need to say anything, as these are of standard types.

My main object in putting before you this synopsis of the appliances that have been evolved in working out the cyanide process of gold extraction is to point out a field in which chemical engineering in the strictest sense of the term has been given free play, and has attained results of quite exceptional importance. I have thought it advisable to draw attention to the mechanical ingenuity that has been displayed in devising methods of dealing with such enormous quantities of both solids and liquids, these being methods and appliances which necessarily lie somewhat outside the experience of the ordinary chemical manufacturer, whilst the scale upon which the operations are conducted is one of altogether unprecedented magnitude. I venture to think that the chemical industry will not only have to evolve new engineering methods in the future, but will have to utilise to the fullest extent all the methods and appliances that have been devised in cognate industries. There can be no doubt that the future of the chemical industry, particularly of the heavy chemical industry, in this country depends essentially upon our being able to compete with our neighbours by producing at least as cheaply as they can, and I venture to suggest that this implies that chemical works will have in the future to be constructed on a scale of magnitude far greater than has been the case heretofore. Furthermore the processes will have to be conducted with a minimum of labour, because labour will in the future not only be scarce, but will be exceedingly dear. I for my part see no reason to expect that wages will ever come down to anything approaching their old level, nor have I any great desire to see them down again to that point, my ideal being rather a properly paid workman, better educated and more intelligent than his predecessor, and above all anxious to give an honest day's work in return for a good day's wage.

I have dwelt upon appliances requiring the minimum of labour because I feel convinced that such appliances must be employed in the chemical industry far more extensively in the future than they have in the past. The substitution of mechanical for manual power necessarily involves an increase in capital outlay, and although capital has gone up in value as well as labour, the latter has risen much more in proportion, so that there is still an important economic advantage to be gained by the introduction of labour-saving appliances. I feel convinced that the chemical industry, along perhaps with all the other industries of the country, can only survive in the fierce economic struggle which will undoubtedly succeed to the present conflict if we are prepared to organise our industries in such a way as to conduct all our operations systematically by means of processes and appliances involving the minimum of unskilled labour, though they may require no inconsiderable amount of intelligent supervision. Such methods do not imply a yet further consideration, perhaps to us in this country the most important of all—namely, the supreme necessity for having at our command sources of extremely cheap power. In the chemical industry, as in every other industry in Great Britain, this is the dominant factor; our national prosperity has been built up essentially on a basis of cheap power, that is to say, on an abundant and low-priced coal supply, and unless we can retain this advantage after the war our outlook for the future will be black indeed. Not only must we take care that we are able to produce coal at least as cheaply as any of our competitors, but also that we utilise it to at least as good advantage. Provided only that we are able to produce power at a reasonable cost, I have no

fear but that British ingenuity, with the powerful aid of the late-born recognition of the important part that scientific education plays in fostering and in applying it, will prove equal to any of the demands that the highly complex requirements of modern advanced industrialism may make upon it.

Dr. T. HOWARD BUTLER, in proposing a hearty vote of thanks to the President for his address, said that it was a great benefit and pleasure to hear such an able survey of a subject such as Prof. Louis had given. He assured the President of the hearty support of the Society. As a member of Council he could say that the large amount of business which the Society had got through during the past year had been not a little due to the admirable way the President had managed affairs.

Dr. F. W. RIXON, in seconding, especially thanked the President for his remarks on the question of the value of scientific research.

The vote was accorded with acclamation.

ELECTION OF COUNCIL.

The report of the scrutineers of the ballot for the election of officers and members of Council showed that the following were elected:—President, Prof. Henry Louis; Vice-Presidents: Dr. E. F. Armstrong, Prof. W. R. Hodgkinson, C.B.E., Robert L. Mond, and Walter F. Reid. Ordinary members of Council: Sir Robert Hadfield, F.R.S., Dr. F. Mollwo Perkin, W. J. A. Butterfield, and C. S. Garland.

ELECTION OF AUDITORS.

On the motion of Dr. J. C. Cain, seconded by Mr. F. W. Attack, Messrs. Price, Waterhouse and Co. were elected auditors to the Society.

VOTE OF THANKS TO UNIVERSITY.

The PRESIDENT expressed the thanks of the Society to Sir Isambard Owen and the authorities of the University for placing the University rooms at their disposal during the period of the meeting.

Sir ISAMBARO OWEN briefly thanked the President.

After the meeting the members were entertained at luncheon at the Grand Hotel by the Local Section, Dr. T. H. Butler being in the chair.

Wednesday afternoon, Thursday, and Friday morning were devoted to the reading and discussion of papers. The discussions on "Copartnership" and on "Industrial Efficiency" will be recorded in a later issue. The remainder of the papers are printed in this issue.

ASPECTS OF THE LOW TEMPERATURE CARBONISATION OF COAL.

BY EDGAR C. EVANS, B.Sc., F.I.C.

The question of the low temperature carbonisation of coal is not a new one; the disadvantages of bituminous coal as a fuel have been recognised from very early times, and as far back as 1656 Evelyn described in his diary a "project by Sir John Winter of charring sea-coale, to burne out the sulphure and render it sweete." The resulting "cinders" made a "cleare pleasant chamber fire, depriv'd of their sulphure and arsenic malignity."

In 1681 a patent was taken out by Becker and Serle for the production of pitch, tar and smokeless fuel from coal, while the Earl of Dundonald took out in 1781 a patent for making pitch, tar, oils, cinders, etc., from coal.

The early literature of the gas industry, from 1792 onwards, teems with references to low temperature carbonisation, but the gas engineer's desire for the utmost yield of gas from his coal

led to the adoption of higher and still higher temperatures, until to-day the highest possible temperatures compatible with the nature of the retort are universally used in this industry.

From the point of view of the gas industry, with gas as the primary product, this choice has been thoroughly justified by the results obtained, and the same thing can be said of the coking industry, where a hard metallurgical coke is the main desideratum.

Neither gas coke nor metallurgical coke, however, is an ideal substance for use as a domestic fuel, and in the modern sense of the term, the idea of low temperature carbonisation is the outcome of attempts that have been made to produce a smokeless fuel from bituminous coal.

In this sense, low temperature carbonisation can be said to date from 1890, when the late Col. Scott Moncrieff suggested the withdrawal of the charge from gas retorts when half the usual quantity of gas had been evolved, with the idea of using it as a domestic fuel. It was found, however, that the only result was the production of a partially coked layer on the outside of the charge with an inner core of practically raw coal.

A more feasible suggestion was made in the same year by Parker, who proposed (Eng. Pat. 67, 1890) to produce a smokeless fuel by passing steam, water gas, or coal gas, superheated to a temperature of 600° to 650° C., through a mass of coal in a retort. The idea of using an inert gas as a heating medium is an excellent one, but it failed in this as in subsequent attempts owing to the peculiar nature of the phenomena connected with the carbonisation of coal at these comparatively low temperatures.

In 1906, Parker took out his famous master patent (Eng. Pat. 14,365, 1906) for the production of "Coalite" by heating coal in the presence of steam to a temperature not exceeding 800° F. A number of retorts were tried, details of which are given in a series of patents taken out between 1906 and 1911. The first proposal was to use Δ -shaped retorts about 5 ft. wide, 7 ft. long, and 16 in. high, the coal being placed in a layer not more than 6 in. thick.

Coal which melted under heat was treated in tapering cylinders about 10–12 in. in diameter, one end being perforated to allow the escape of the gases produced, or it was heated in completely filled tubes of not more than 6 in. in diameter.

These experiments failed, however, and the next step was to use a narrow vertical retort of oblong cross section, which again was replaced by bunches of vertical tubes, each tube being from 4 to 6 in. in diameter, and each separate battery of tubes being connected by means of a separate pipe with the hydraulic main. In a later patent, these tubes were provided with slots by means of which communication was established between adjacent tubes, so that if one of the tubes became temporarily choked, the gas evolved could pass up the other.

This gradual alteration in the design furnishes an interesting commentary upon the difficulties experienced by the Coalite company, and these proved so great, that despite the assistance of some of the best scientific brains of the country, and the expenditure of large sums of money, the process failed to satisfy commercial requirements.

The Coalite failure, however, served one good purpose—it created a popular interest in coal carbonisation, it showed the need that existed for a free-burning smokeless fuel, and cleared up many obscure points in coal carbonisation.

A considerable amount of work has since been performed on low temperature carbonisation both from a scientific and a technical standpoint, and, whilst commercial success has yet to be realised, a number of the problems involved have proved capable of solution on a semi-commercial scale.

The question of commercial success by any system capable of general application is not an easy one. The process of coal carbonisation itself is a most complicated one, and it is rendered still more complex by the wide differences that exist between different coals.

Constitution of coal.

The whole phenomena of coal carbonisation at low temperatures are intimately bound up with the constitution of the coal that is treated, and, in the solution of the problem, the most important requirement is a clear understanding of the nature of coal itself. Unfortunately this is extremely difficult to obtain by purely chemical methods. The brilliant researches of Wheeler and his collaborators have established the fact that coal contains two classes of substances, viz.:—Resinous substances derived from the resins and gums of the vegetation from which the coal was originally formed, and cellulosic or "humic" compounds derived from the cellulose of the original vegetation. Some of the conclusions of Wheeler and his co-workers are still the subject of debate, but the following distinctive properties of these two classes of substances are agreed to by most of the workers in this field.

Cellulosic or "humic" compounds:—(1) Are infusible. (2) Yield very small quantities of liquid distillates on being heated, these consisting chiefly of phenolic compounds. (3) Are insoluble in chloroform.

Resinous substances:—(1) Have a low melting point. (2) Yield a large proportion of liquid products on distillation, these consisting below 500° C. chiefly of paraffins, naphthenes, and members of the olefine series. (3) Are soluble in chloroform, phenol, pyridine, and certain other solvents. (4) Leave on heating to 500°, a pitch which acts as a binding constituent in the formation of coke.

At first sight, it might seem possible to consider all coals as being made up of varying proportions of resinous and cellulosic or humic material, and that the properties of any coal would depend essentially on the relative proportions of these two substances that it contains. Such a constitution would, however, by no means account for the differences found in different coals. In the first place, neither resins nor cellulose contain sulphur and nitrogen, and the organic sulphur and nitrogen compounds of coal would still require a place in the essential constituents of the coal. Secondly the properties of non-coking cannel and spore coals could not be reconciled very easily with a constitution based only on resinous and humic substances.

It is therefore essential to widen our ideas of the constitution of coal to include substances other than these two, or else to broaden the terms to include substances widely differing both in constitution and in properties. Unfortunately, purely chemical methods have exhibited very serious limitations in the examination of the exceedingly complex mixture of substances contained in coal, and a clearer conception of the rational constitution of coal can probably be gained much more easily by a combination of chemical and microscopical methods.

The pioneer work of Lomax, followed by the researches of Stopes, Hickling, and others in this country, of Renault and Bertrand in France, and of White, Jeffreys and Thiessen in America have thrown considerable light on the constitution of coal. It is impossible to go into their researches in detail, but essentially, in the light of the microscopic examination of coal sections, coal can be regarded as being made up of varying proportions of humic matter, resinous substances, and cuticular substances, the last-named embracing spores, spore cases, etc. (including probably the so-called algae noted by Bertrand and Renault in cannel), and the

resistant cuticles of the original vegetation. To these can probably be added the nitrogenous and organo-sulphur compounds in the coal which presumably would have been derived from the cell contents of the parent vegetation.

It is impossible in this paper to discuss the latter substances in detail, but, from the point of view of carbonisation it is of considerable importance to gain an idea of the nature of the cuticular material in coal. At first sight, it would seem probable that this would be resinous in character; under the microscope it appears as a bright yellow substance resembling very closely the resinous particles in the coal, but so far as the author is aware, the small amount of work that has been performed in this direction seems to indicate that cuticular matter in general is non-resinous in character, or at any rate, if it is resinous, it differs in many important respects from the customary resinous constituents.

In an unpublished paper read by Lomax before the Manchester Geological Society in 1914, it was shown that spore coals were non-coking in character, and this was confirmed by Lomax and the author in an examination of the Lantern Seam of the South Rhondda Colliery. This seam is highly resinous in its general character; when distilled at temperatures of 500° to 550° C., it swelled, fused, and gave a considerable proportion of liquid distillates that were not phenolic in character. When the seam was examined in detail, however, it was found that those portions which were made up of spore coals were non-expanding, non-fusible, and except in places where resins were clearly evident, non-coking in the customary sense of the term. It appears likely therefore that the cuticular ingredients of coal are non-resinous. On the other hand, they have properties that are different from the purely humic constituents. Spore coals, even though they are non-coking, yield a large proportion of paraffin compounds on distillation at low temperatures, and this fact, together with their resistance to decay, seems to indicate a non-cellulosic origin.

Unfortunately, very little detailed work has been done as far as the investigation of the cuticular portions of living plants is concerned, but apparently they consist of cellulose combined with fatty and waxy compounds of very high molecular weight. Such a composition would account for the properties possessed by spore coals, but the exact nature of the residual product as it exists in coal has yet to be determined.

Theory of the coking process.

As far as the coking property of coal is concerned, the predominant factor is undoubtedly the proportion and character of the resinous constituents that it contains. Parr and Olin (Bulletin 60, University of Illinois) as the result of a study of the low temperature distillation of Illinois coals, put forward the following hypothetical conditions as being necessary for the formation of coke:—(1) There must be present certain substances which have a definite melting point; (2) the temperature of decomposition of these substances must be above the melting point; (3) when the compounds that satisfy the first and second conditions are unsaturated, it is possible by subjecting them to oxidation so to lower the temperature of decomposition that the second condition is no longer fulfilled, in which case coking will not occur. These hypotheses seem to agree very well with the known data concerning the coking process, and, while the phenomena involved are exceedingly complicated, a fair idea can be obtained with their aid of the reactions that take place within the coking chamber.

It is necessary at the outset to distinguish between high and low temperature carbonisation. In the

former case, not only is the reaction complicated by secondary reactions taking place between the liquid and gaseous products at temperatures above 700° C., but there is a considerable physical difference in the structure of the resulting coke product. The secondary reactions of the liquid and gaseous products have already been very ably dealt with, and it is therefore advisable in these notes to consider only those factors that are involved in the production of coke.

As far as coke formation is concerned, the use of a high temperature simplifies the process considerably and actually reduces the number of factors that have to be considered in large scale operations.

When a charge of bituminous small coal is introduced into a coking chamber the walls of which are maintained at a temperature of say 1000° C., the outer layers become rapidly heated until, at a temperature of 300° to 400° C., they soften owing to the fusion of the resinous substances. The temperature rises too rapidly for this condition to last very long, however, and gas begins to be evolved, the evolution increasing rapidly as the temperature rises, until finally the portions nearest the wall solidify. Gas still continues to be evolved from the solidified portion, and continues in fact until the coke reaches the temperature of the walls, and even then, at 1000° C., there is still left a small quantity of volatile matter which could only be expelled by raising the temperature considerably.

Meanwhile, the adjacent layers towards the centre of the oven have attained the pasty stage, and gas begins to be evolved which passes principally through the porous, solid, outer layers to the wall of the oven. (Cf. Lewes, "Carbonisation of coal," Young, J. Gas Lighting, 1912, 119, and Evans, J. Gas Lighting, 1913, 587.) A small amount possibly given off from the inner portion of the pasty mass, may pass upwards through the central core of raw coal, but this quantity would not be very great. As the gases pass through the outer solid coke, the hydrocarbons are decomposed to a certain extent with the formation of carbon which is deposited on the outer layers, thus forming a stronger, harder coke.

Essentially the coking process resolves itself into the formation of a pasty zone, which, fairly rapidly at first, but afterwards with continually decreasing speed, travels towards the centre of the oven. The rate of advance of the zone depends on the temperature of the oven walls and the thickness of the charge. The higher the temperature, the more rapidly does the fused zone pass towards the centre of the oven. In the later stages of the carbonisation the rate of progress becomes very slow. It has been shown by Simmersbach, that in a coke-oven 20 in. wide, the centre of the charge remained at a temperature of 10° C. for 2 hours after charging, then rose to 100° and remained there for 13 hours, while even after 20 hours the temperature was only 410° C. (cf. Ramsburg and Sperr, J. Franklin Inst., Apr., 1917).

As the coking process continues, the coke becomes fissured along lines perpendicular to the walls of the oven, and finally when the fused zones reach the centre of the oven, the resistance of the outer layers becomes greater than the resistance towards the centre of the charge, and a considerable proportion of the gas evolved passes up the centre of the charge, the coke dividing into two distinct masses.

Low temperature carbonisation.

In its main essentials, the process of low temperature carbonisation proceeds along similar lines to the above, but several of the factors involved are so intensified that a radical alteration in the design of the oven is necessary for the process to be carried out on anything like a commercial scale. The following notes summarise the main differences.

(1) The low temperature (450°–550° C.) of the walls of the oven reduces enormously the rate of transmission of heat through the charge, or in other words, it reduces the velocity of the zone of fusion. For this reason, a thickness of four to five inches is the maximum that can be treated in stationary charges within economical limits of time. This factor brings in its train the following results:—(a) The capital outlay is increased owing to the increase in the number of units, (b) labour charges are necessarily increased, (c) the space taken up by the plant is increased, and (d) the maintenance cost is increased.

(2) The resistance of the fused zone to the passage of gas is enormously increased as the temperature diminishes. It has been estimated by O. B. Evans (J. Gas Lighting, 1913, 587) that the resistance offered to the passage of gas at 540° C. is about 7 times greater than at 700° C. Owing to this extremely high resistance, if for any reason the outer zone becomes choked, the gas accumulates in the charge to such an extent that serious gas pressures are developed. In several cases the author has found that when dealing with resinous coals, the gas escapes from the central portion of the charge not in a direction at right angles to the containing walls, but parallel to them, so that the resulting coke appears as if it were built up of extremely thin layers. This seems to indicate that in low temperature carbonisation, the outer layers are much more resistant to the passage of gas than is the case in high temperature carbonisation.

(3) The time during which the coal is in a state of semi-fusion is considerably prolonged.

In the case of high temperature carbonisation the time-temperature gradient is rather steep, and the interval of time during which the coal is in a state of fusion is comparatively short. In the case of low temperature carbonisation, however, this period is considerably prolonged and owing to this prolongation of the pasty stage, with the high pressures that are induced in the coal mass, the cell cavities in low temperature coke are considerably larger than is the case with high temperature coke. This produces ultimately a considerable expansion in the coke, an expansion often great enough in the case of some resinous coals and with well filled retorts to choke up the gas outlet completely. With such coals a considerable space must be left in the retorts to allow room for expansion, and the economic efficiency of the process is thus seriously affected. Further, the coke becomes porous and friable.

(4) Any free space left at the top of the coal charge increases the amount of air that is left in contact with the coal. This exerts a most deleterious action when the coal is carbonised at low temperatures and results in the formation of a friable, powdery coke.

It is evident that the low temperature carbonisation of bituminous (caking) coal involves the solution of a number of problems many of which are of a most conflicting character. The records of the Patent Office contain a number of attempts to solve these problems and of these, three main classes can be distinguished, *viz.*:—

(1) The use of externally heated, intermittently charged retorts.

(2) The use of intermittently charged retorts, internally heated.

(3) Continuous processes, in which the coal charge is carried forward by automatic means through a retort which may be heated either externally or internally, or by a combination of both methods.

Externally heated retorts. The various types of "Coallite" retorts are on the whole typical examples of low temperature retorts. Their failure was due to the lack of detailed knowledge regarding the constitution of coal, and also to the difficulty

of adapting the system for carbonisation on a commercial scale. The Coalite trials proved one thing very clearly, however, and that was the necessity of carbonising the coal in layers as thin as was compatible with commercial requirements. This result is achieved in a very simple manner by the Tozer retort of the Tarless Fuel Company. In this retort, the coal is charged in concentric layers, so arranged that no layer is more than 4–5 in. thick. It is obvious that much larger charges can be got into the same space than in the coalite process, the coal can be charged much more readily, labour charges for handling are reduced, and the heating of the retorts can be made very uniform.

The retorts are used in conjunction with Simpson's process for heating coal under a vacuum of from 20 to 26 in. of mercury. The use of such a high degree of exhaustion has certain obvious advantages. The oxygen left in the retort after charging is reduced to a minimum, the liquid and gaseous products would be removed very rapidly from the retort and possibly distillation would be effected more readily. The influence of the vacuum on the quality of the coke produced is not clear. Porter and Taylor state (Tech. Paper 140, U.S. Bureau of Mines) that Pittsburg bituminous coal yielded a light, inferior, porous coke when slowly heated at atmospheric pressure, but at a pressure of less than 30 mm. it produced a dense coke. The reason for this is not very clear, but apparently the use of a vacuum produced a decrease in the tenacity of the tar film.

On the whole a vacuum process offers certain advantages over those carried on at atmospheric pressure, but on the other hand, from a commercial standpoint it has certain disadvantages which are obvious to workers familiar with coal carbonisation on a large scale. These can be summarised thus:—(1) Increased capital outlay; (2) Increased power consumption; (3) difficulty of avoiding leakage (this would be a difficult matter under works conditions, especially when working on a big scale with unskilled labour in a colliery district liable to subsidence).

Taking the Tarless Fuel process as a whole, it is attractive in many respects, but it has yet to prove its capacity for satisfying commercial requirements on a big scale.

A process that has attracted considerable attention is that carried on by the Barnsley Smokeless Fuel Company. This differs in many essential aspects from customary low temperature practice, and it might perhaps be briefly dealt with. In the first place the Barnsley retorts are made of fireclay instead of cast iron, the usual material used in low temperature retorts. Cast iron is certainly not an ideal material; its disadvantages were early recognised by the gas industry and led to its substitution by clay retorts. In the Barnsley plant vertical retorts of rectangular cross section are used which are somewhat wider than those used in most low temperature processes. In these (Eng. Pat. 108,200) four varying zones of heat were maintained, the lowest being at a temperature of about 450° C., the next 500°, the next 550°, etc., whilst finally, in the free space at the top of the charge, a temperature of 900° to 1200° C. was maintained. In this space was suspended a grid made of some suitable material (metal, metal oxide, fireclay, or carbon) so that the gaseous compounds of distillation were subjected over as great an area of contact as possible to the temperature necessary to convert the paraffinoid tars to aromatic hydrocarbons.

The author has had no experience of this plant, but from purely theoretical considerations the chances of success would be small if the above temperatures were adhered to. In the first place, the retorts are wider at the bottom, so that the

zones maintained at the lowest temperatures are actually wider than those at higher temperatures. Thus the top portions would be carbonised much sooner than the lower portions, so that assuming that the lower layers could be carbonised in economic limits of time (which is doubtful) the result would be the formation of a mass of coke of very uneven quality, the lower layers spongy and porous, whilst the top layers would probably be difficult to burn. It is also difficult to see how the dangers of a serious accumulation of gas could be avoided in the lower portions, and the conditions in this respect would probably be worse even than in the "Coalite" retorts. However, the author has had no experience of the process and it would be interesting to learn something of the results that have been obtained.

A number of other examples of low temperature retorts could be given, but, taking them as a type, they possess the following disadvantages, arising mainly from the necessity of having to work with charges of coal that are neither too wide nor too high. The number of units must be considerably greater than is the case in high temperature practice, and this involves increased capital outlay, increased labour charges, increased repair costs, and a lowering of the general economic efficiency of the plant.

Internally heated retorts. In this type, the coal charge is heated by the actual passage through it of inert gas preheated to a temperature sufficiently high to carbonise the charge. On purely theoretical grounds, this proposal is extremely attractive. The bulk of the time occupied in present systems of carbonisation is taken up in heating the innermost layers of the coal, and if these could be heated from the outset considerable economies in time could be effected. A considerable number of attempts have been made to carbonise coal by passing through it a current of inert gas heated to a temperature of from 400° to 600° C., and Parr and Olin (Bull. 60, Univ. of Illinois) had some excellent results on a small scale by this method.

As far back as 1890, Parker (Eng. Pat. 67, 1890) proposed to pass steam, water-gas or some other suitable gas superheated to 500°–600° C., with a view to making smokeless fuel, and a number of other inventors have followed along similar lines. In the case of bituminous (resinous) coals, the old difficulty arises that when the coal reaches the pasty stage, it becomes impervious to the passage of the gas, but there seems to be no reason why the method should not be used for shales, cannel, or for coals that are not fusible.

The results obtained by McLaurin with a process of this type (this J., 1917, 620) are extremely interesting. As would be expected, cannel coal proved to be quite easy to work when carbonised by means of a stream of hot producer gas, but it was also found that Cadder coking coal if screened came out of the retort in the same shape and same size as it was put in. McLaurin suggests that this is due to the slow heating to which the coal was subjected and that under those conditions it did not intumescence. If this condition is applicable to all coals, it opens up possibilities of an extremely interesting character. The author, however, has not found it possible to repeat this result with the highly resinous coals of South Wales, except under conditions in which oxygen was present in the heating gaseous medium. The effect of oxygen when coal is carbonised at low temperatures has already been discussed, and the author is inclined to believe that the small quantity of oxygen which would be present in the hot producer gas in McLaurin's experiments played as important a part as the slow heating. A typical analysis of the producer gas gave 0.9%

of oxygen, so that there seems to be every reason for believing that the coal was carbonised in an atmosphere containing a small proportion of this gas, an idea which is confirmed by a study of the properties of the tars obtained.

Another proposal of this type is that given by Lamplough (Eng. Pat. 108,343, 1917), the heating medium in this case being steam.

On the whole, internal heating seems to offer considerable possibilities in the treatment of shales, cannel, and possibly certain types of coal if carefully screened, but as McLaurin and others have found, difficulties would arise in the carbonisation of fine coal in this way. There is perhaps one point that would need consideration, and that is, if a small proportion of oxygen were systematically introduced into the heating gas, what would be the effect upon the tars produced? These apparently would have a similar composition to the old Jameson tars, which were produced under conditions theoretically analogous to those existing in McLaurin's process.

Continuous processes. The third class of retort which has been proposed for the low temperature carbonisation of coal is that in which the coal is carried forward through the furnace by means of a conveying system.

The Archimedean screw has been suggested as a suitable carrier for quite a long time. A most interesting anticipation of one of the most modern of these systems is given in Patison's Eng. Pat. 569, 1873, in which coal, shale, or other fuel is carried through a heated retort by means of a worm conveyor. For low temperatures—with a high oil yield—the inventor proposed to use a cast iron retort, but for high temperatures he suggested the use of a fireclay furnace.

The well-known Del Monte system differs only slightly from this system, but it had one innovation, and that was in the use of a screw mounted on a hollow shaft, which was heated internally by a row of jets from a central gas pipe. Further, the coal was subjected to a fractional distillation, one end of the retort being maintained at a considerably lower temperature than the other. This retort again could be used for wood, shale, lignite, or peat, but with coking coals, the swollen pasty mass which was produced completely prevented the working of the screw.

It seems difficult to believe that any system which involves the stirring up of the coal in any way can be used for bituminous coals, and for that reason, it is doubtful whether a continuous system on the lines of the Woodhall-Duckham or the Glover-West retorts can be used for the low temperature carbonisation of these coals, except perhaps under conditions already touched upon.

On the other hand, there seems to be no reason—apart from those connected with engineering difficulties—why the coal should not be conveyed through a furnace, by some system in which the coal itself is not stirred.

A system of this type that has been worked with some degree of success, is that introduced by Pringle and Richards. In this the coal is carried by means of an endless conveyor through a retort the temperature of which is maintained at about 500° C. The conveyor itself is fitted with compartments so as to subdivide the coal into a number of separate small charges each of which is rapidly heated to the desired temperature. The coal itself is undisturbed in its passage through the retort, and leaves as a porous semi-coke which is an excellent domestic fuel. This process as yet has only been worked on an experimental scale; the obvious difficulties are of an engineering character and whether or not they can be overcome on a large scale plant remains to be proved.

A system of this type seems to offer several advantages for low temperature carbonisation; temperature control could be readily effected, labour charges would be low, and by suitable engineering methods the rather heavy capital outlay and high maintenance and repair costs which would probably be inherent in this particular system could be reduced to a limit which would make it a commercial proposition.

A number of other proposals could be given, but as yet, not one of them has been tested on a commercial scale. As far as the author can see, there does not seem to be any overwhelming difficulties in the way of the low temperature carbonisation of shales, lignites, cannel, etc., whilst for resinous coals, success will probably be attained only by an individual study of the coals it is desired to treat, accompanied possibly by a suitable preliminary treatment which will give a final product of sufficient solidity and strength to withstand customary conditions of handling and transport. In this connection the briquetting of the coal either before or after carbonisation will have to receive very serious consideration. The main considerations in this direction are economic in character and in the present artificial conditions prevailing in the coal market it would be extremely difficult to estimate the commercial possibilities of such a combination.

Economics of low temperature carbonisation. An attempt might, however, be made to review from a general standpoint the financial possibilities of low temperature carbonisation, and this perhaps is all the more necessary because of the extravagant estimates that are periodically issued from certain sections of the financial press. In this connection it must not be overlooked that there are many coals which are almost unusable in the raw state, and in some cases even there are whole coalfields in which the coal is of such quality that under the economic and geographical conditions prevailing in their immediate vicinity they are commercially unworkable. Several such cases have been brought to the author's notice in which a well designed system of low temperature carbonisation would result in the economic salvation of the coalfield. Disregarding for the present these exceptional cases, there remain two or perhaps three main directions in which the adoption of low temperature carbonisation has been strenuously advocated.

The first is in the treatment of cannel coal. From a technical standpoint this does not appear to present any very serious difficulties, and the question practically resolves itself into a commercial one. The matter has already been fully treated recently ("A New British Oil Industry," Craig, Perkin, Berry, and Dunstan, J. Inst. Petrol. Tech., Apr., 1918) and need not be discussed here. In this case, however, the utilisation of the residue is the factor upon which the success or failure commercially depends. The method usually suggested is to gasify the residue in producers of the Mond type and recover the ammonia produced (see Paton, Iron and Coal Trades Review, Mar. 22, 1918, and "Fuel Economy," paper read before Birmingham Section, Inst. Elect. Eng., 1917). Technically such a process would be ideal, especially if the carbonisation and gasification could be performed in one plant as proposed by McLaurin (this J., 1917, 620) or Wollaston (Eng. Pat. 111,964, 1918); there is one point which needs to be emphasised, the necessity for considering the Haber process as a factor in the reduction of price of ammonium sulphate after the war. It is estimated by the Barrett Company of New York, that the production of ammonia from this process alone amounted in 1917 in Germany to a quantity

equivalent to over 1,000,000 tons per annum of ammonium sulphate. The world demand for this fertiliser is increasing rapidly, and there is every prospect of a still further increase during the next few years, but with a competitor of this magnitude in the field, there is every need for caution in considering the claims of the recovery producer against the cheaper and technically more efficient non-recovery producer.

There is one other point that can be only briefly dealt with, and that is the relation of the gas industry to low temperature carbonisation. In the author's opinion, the gas engineer, to whom gas is the main and primary product, is quite justified in adhering to high temperatures in general practice. The yield of gas in low temperature carbonisation is far too low to make it attractive to the gas engineer, and with humic coals this small quantity is seriously contaminated with carbon dioxide. Further, to attain a total yield comparable with present practice, the capital outlay would be considerably increased, the space required for the plant would be very much greater than in present practice, and the labour costs (per 1000 cub. ft. of gas) would be enormously increased.

There are of course advantages in favour of low temperature practice, but in view of the standardised conditions prevailing in the gas industry, with works already cramped for space in many cases, and with heavy capital charges on plant already installed, it is extremely difficult to see where its advantages come in. Gas coke is certainly not an ideal product either from a domestic or an industrial standpoint, but by suitable preliminary treatment of the coal used, even this can be made an excellent free-burning product; and if the market conditions allow, the gas engineer can always erect additional plant for this purpose. Apart entirely from any preliminary treatment, however, the uses of gas coke are rapidly extending and before long it should cease to be the drug on the market that it has been in the past.

Taking everything into consideration, the gas engineer is well advised in rejecting low temperature carbonisation as being unsuitable for the purpose of producing gas in as great a quantity and of as high a quality as possible.

There remains the last and greatest aspect of the question—the low temperature carbonisation of bituminous small coal. The total quantity of coal raised in the United Kingdom in 1916 was approximately 256,000,000 tons. Of this, 37,600,000 tons was carbonised yielding something over 8,000,000 tons of gas coke and 13,200,000 tons of metallurgical coke. Of the remaining 218,400,000 tons, allowing $4\frac{1}{2}$ million tons of anthracite and say 30 million tons of low volatile coals, there remains nearly 184 million tons of bituminous coal, of which over 60,000,000 tons would be small coal.

The use of raw coal was characterised over thirty years ago as a barbarous procedure; the statement is true to-day, but it has gained an enormously greater force as the result of our experience during the past four years. Disregarding for the time being the idea of carbonising large coal as being too great a feat of mental gymnastics for the average commercial mind to attempt, there remains the fact that there is available in this country approximately 60 million tons per annum of bituminous small coal, all of which, under certain well-defined conditions, can be carbonised to leave a coherent, solid, free-burning smokeless residual fuel, which in many respects is superior to the large coal from which it is produced.

With this as a basis, and with the further consideration of the necessity for this country to be self-supporting in the ever increasingly important

matter of liquid fuel, it is evident that there is an enormous scope for the introduction of a successful system of low temperature carbonisation. The main question unfortunately is, will it pay?

Under present conditions of scarcity of coal, of steel, of raw materials and of labour, it is an extremely difficult matter to draw up an estimate which would hold good for possibly more than a few months, but a provisional estimate can be attempted (using pre-war figures) which might serve as a basis for future guidance.

Cost of plant.

This would depend on the type of installation that would be found serviceable. At first sight a low temperature plant working at only 500° C. would be less costly than a coke-oven plant working at 1000°. If the stationary type of retort were erected, this factor would be counterbalanced by the greater number of units found necessary, whilst the price of a continuous retort would be increased owing to the engineering devices found necessary. The cost of a 300 tons a day coking plant before the war would be approximately £50,000 to £60,000, and this figure has been taken as representing the capital outlay.

Coal. The value of the coal and the resulting fuel would be interdependent; for that reason, the price of the coal has been arbitrarily fixed at 10s. per ton of unwashed small.

Labour is figured at 2s. per ton of coal carbonised.

Power, steam, etc. This figure would again vary with the type of plant erected. In a vacuum plant the power consumption would exceed that of a coke-oven plant, and the same thing would apply in the case of certain types of continuous plants. For purposes of estimation the figure of 4d. per ton has been taken as the cost of steam and power.

Repairs and maintenance. The advantages of working at low temperatures would in this case again be counterbalanced by the increased number of units. In the case of continuous plants this figure would probably be high, but it would be counterbalanced by reduced labour charges.

Depreciation and interest is assumed to be 15%.

Stores, etc. A figure of 2d. per ton has been assumed.

The following is an estimate of the expenditure in a plant carbonising 300 tons of coal per day. Assuming 300 working days a year, 90,000 tons of coal per annum would be treated.

Coal washing. Assume unwashed coal at 10s. per ton. Cost of washing 6d. per ton. Assume 25% loss in washing. Then cost of coal to ovens=14s.

<i>Expenditure.</i>	<i>£</i>
Coal, 90,000 tons at 14s.	63,000
Labour	9,000
Repairs and maintenance	1,500
Steam and power	1,500
Interest and depreciation ..	9,000
Stores	750
	<hr/>
	£84,750

Receipts would be made up of the values of the coke, tar, sulphate of ammonia, and light spirit produced.

Coke. The character of the resulting smokeless fuel would depend on a number of factors, the most important being the nature of the coal used, temperature of carbonisation, time of carbonisation, thickness of coal charge, type of retort used, and gas pressure under which carbonisation is effected. Of these the first is easily the most important. As a general rule the coke from highly

oxygenated coals (humic coals) has a higher calorific value than the coals themselves, while with other coals the calorific value is lower. Further, humic coals yield a friable powdery coke, whilst resinous coals yield a porous coke which is, however, fairly strong if carbonised under suitable conditions.

By judiciously mixing the coals used an excellent product can be obtained which has qualities which make it superior even to the large coal. In most low temperature schemes it is assumed that the resulting fuel has a value (on a pre-war basis) of from 25s. to 35s., but if low temperature carbonisation were adopted on a large scale it is extremely doubtful whether the price would be much greater than that of the large coal.

As a general rule the difference in price between large and small coal varies from 7s. to 10s. per ton. With the small coal in this case at 10s. per ton, and allowing for the fact that it has been washed, it is perfectly justifiable to take the value of the resulting fuel at 20s. per ton.

For purposes of this estimate it is assumed that the yield of large fuel is 70%, together with 10% of breeze. The breeze could probably be reduced by the preliminary preparation, but even then it would be higher than is the case in coking practice.

The value of the breeze is taken as being equal to that of the initial unwashed small coal.

Tar. The value of this substance is difficult to ascertain under present conditions. Further, the cost of purification is difficult to calculate. The process of purification will have to be worked out very carefully, otherwise the percentage losses would be very high. Taking its constituents in detail, however, the probability is that the substance will prove to be a valuable product. Tar acids to-day are, of course, at a high figure, but even after the war there will be a heavy demand for creosoting materials, and this constituent of the tar will therefore probably prove valuable. The light oils and middle oils of the tar would probably attain a fair price owing to the growing demand for petroleum products of all kinds. The value of the pitch is at present an unknown quantity. With its freedom from so-called free carbon and a constitution more nearly approaching oil pitch than coal-tar pitch, there seems to be every prospect of its finding a ready market. Taken altogether, the value of low-temperature tar would probably prove to be at least as high as that of high-temperature tar; it may easily be higher, but to be on the safe side a value of 2d. per gallon has been assumed, with a yield of 15 gallons per ton of coal carbonised.

Light spirit should prove an excellent motor spirit. A yield of 2 gallons a ton is assumed, and a value of 1s. per gallon.

Sulphate of ammonia. The yield of this substance varies considerably with different coals, and rapidly rises after a temperature of 500° C. is passed. As far as the author's experience goes, the yield of ammonia at 500° C. is considerably lower than the 20 to 30 lb. per ton of coal usually quoted, and a figure of only 10 lb. per ton of coal has therefore been taken for purposes of this estimate.

Gas. The yield of gas at 500° C. is usually given as 5000 cubic feet per ton. This again is considerably higher than the quantity found by the author with most coals. Humic coals sometimes yield large quantities of gas at low temperatures, but this is often contaminated with high percentages of carbon dioxide. On the whole it is better to assume a gas yield sufficient to heat the oven, but insufficient to give any surplus.

On the basis of these assumptions the revenue side of the accounts gives the following figures:—

Receipts.

	£
Coke, 63,000 tons at £1	63,000
Breeze, 9000 tons at 10s.	4,500
Tar, 1,350,000 gallons at 2d.	11,250
Light spirit, 180,000 galls. at 1s.	9,000
Sulphate of ammonia, 400 tons at £10 per ton	4,000
	<hr/>
	£91,750

Profit per annum, £7,000.

The resulting profit can scarcely be described as startling, and it certainly does not attain the glowing dimensions generally promised in the initial prospectuses of companies interested in low temperature carbonisation.

On the other hand the figures are distinctly conservative, and err probably on the low side. There is also ample room for improvement on both the debit and the credit sides of the account. Reduced labour and capital charges would make a great difference to the cost sheet. On the other side also there is ample scope for considerably improved figures. As far as the carbonisation of bituminous coal is concerned, the author is not inclined to fix too high a value for the tar. The profits will be made primarily on the solid fuel; the Coalite process certainly showed that there was a demand for smokeless fuel, and if the country wants this fuel it will certainly pay for it. There is no reason also why the temperature should be limited to the 500° C. assumed in the above estimate. This figure has been selected because the solid residue at that temperature is a free-burning, easily ignitable product. But, under certain conditions, the carbonisation temperature could be increased considerably beyond 500° and still leave an excellent fuel. The finest domestic fuel ever tested by the author had been carbonised at temperatures up to 800° C., and contained only 4% of volatile matter. The author is of opinion that the logical line of development in coal carbonisation lies in the direction of a fractional distillation of the coal, the tars being extracted at a temperature sufficiently low to avoid the possibility of secondary reactions, and the temperature afterwards raised to drive off the ammonia and a large proportion of the gas. Such a procedure would not only increase the yield of by-products, but would result in a firmer and denser coke with a consequent considerably reduced proportion of breeze.

Lastly there is the question of the coal used. The estimate has been based on the use of high-grade small coal (an unwashed small coal fetching a pre-war price of 10s. per ton can certainly be considered a fairly good product). There are coals (like Yorkshire unwashed smudge, for example) which sold in pre-war days for considerably less than this figure, and in such cases low temperature carbonisation offers a prospect of an excellent financial return.

Coals from coalfields of the type represented by the South Crop of the S. Wales and Monmouthshire coalfield are excellent in many respects; they are highly resinous, they possess excellent coking properties, they can be cheaply mined, and are situated in an area offering exceptional facilities for export. But unfortunately the coals of this area suffer from certain serious disadvantages. The higher seams contain a high percentage of sulphur, the lower ones are high in phosphorus—two factors which militate seriously against the use of the coal for the production of metallurgical coke. Further, the coal as mined contains an excessive proportion of small coal, a fairly average figure being 30% of large and 70% of small, the latter containing a large

percentage of duff coal. In a case of this kind the advantages of low temperature carbonisation for the primary purpose of yielding a smokeless fuel are obvious; the perfection of a commercially successful system would immediately render feasible the commercial development of this section of the coalfield.

Taking everything into consideration, the subject is one that is worthy of the serious attention of the industrial chemist. A system capable of dealing on a commercial scale with all kinds of coal may perhaps not yet have been perfected, the problems involved—and they are serious problems—may not have been completely solved, but, with a detailed preliminary study of the coal which it is proposed to treat, with an accurate knowledge of the conditions involved in its carbonisation, and with the whole-hearted co-operation of the chemist who investigates those conditions with the engineer who has to meet them, there is no reason why this last resting place of so many lost hopes should not attain an ultimate success which will give it a position of predominant importance in the mining and chemical industries.

DISCUSSION.

Dr. E. F. ARMSTRONG said that he feared that progress in this subject had perhaps been retarded by prejudice. The whole question of low temperature carbonisation had been the subject of such fierce controversy that it might have had some effect on its progress. Insufficient attention had been paid to the scientific basis of the subject. The question was an economic one. The monetary prize for success was small and not very attractive, and it was highly satisfactory that one of the first steps of the new Council of Industrial Research should have been to start a laboratory for the investigation of these problems.

Mr. W. J. A. BUTTERFIELD said that, as the author pointed out, it was almost impossible to say that any one type of retort or process would deal with the many varying types of coal and cannel that had to be dealt with. That applied particularly to the solid residue. The caking coals undoubtedly needed from the standpoint of fuel a different type of retort to a non-caking coal. The continuously fed retort, such as the Del Monte, could only be applied with some modification to caking materials. The disadvantage of the residue from caking coals was its bulkiness; it shared that with gas coke. All the apparatus used with it needed to be almost double the size. When using it for hot water pipes, for instance, an ordinary anthracite stove of half the dimensions would do the same work as one fed with coke. The same applied to transport, wagons, storage space, and handling. He did not think sufficient attention had been paid to the possibilities of utilising the low-ash non-caking coals of the Midlands where there was a powdery residue which it was quite possible to briquette into a material as dense as coal forming a very good domestic fuel. Moreover these were easier to handle in the carbonising plant. The temperature zones that were adopted in the Barnsley retort were very near to gasworks practice, and it was a curious commentary on the previous history of low temperature carbonisation processes that it should have been necessary to use high temperature zones in order to convert the paraffinoid hydrocarbons into aromatic hydrocarbons because of the greater stability of the latter. Some of the spirits that had been produced by low temperature carbonisation were entirely unstable, and became gelatinous after a short time. There were undoubtedly many cannels which it would pay to carbonise for the sake of the oil yield, disregarding the residue altogether. From the fuel standpoint, the prospects

of utilising residues in such cases in ammonia recovery plants after the war were not very great, but there were other cases where the coal was high in nitrogen, such as the very large amount of small coal at the pit's mouth, which it might pay very well to use in agricultural countries.

Capt. C. J. GOONWIX said he had no doubt that pulverised coal would play a very important part in the future. The semi-carbonised fuel produced in low temperature carbonisation plants was extremely bulky and somewhat friable, and he believed that in the transport of this material there would be a considerable amount of dust which would be valueless as far as its use for domestic purposes was concerned. The possibility of collecting this dust in central places and using it industrially as powdered fuel seemed to present a good future if low temperature carbonisation were more generally adopted. He suggested that some experimental work should be done on the use of powdered coal in the Boncourt boiler.

Dr. F. MOLLWO PERKIN said that low temperature carbonisation work was rather more forward than the paper indicated. For example, the Government was putting up near Nottingham a battery of retorts on the Del Monte system. That process, as the author had said, could only be used on non-caking coal. One great objection to the screw system was that in order to carry the coal forward the screw had to be put very close against the edge of the retort, consequently a very fine residue came through at the other end and the only way to work that satisfactorily would be to briquette it. The Tozer retort, in which a vacuum was used, would deal with any class of coal, either caking or non-caking, and it was rarely that he had had any trouble in getting coal out. It swelled up quickly and he thought that the action of the vacuum caused the heat to pass through the coal more rapidly and it gave a really good fuel. With regard to the friability of smokeless fuel, he had recently had a consignment from the Tarless Fuel Co. which had been three weeks on the railway in frosty weather, and it only contained about 10% of breeze, and even this was not wasted because it could readily be briquetted. The Pringle-Richards retort had been considerably improved lately, and it would probably turn out to be a commercial success. It really was a grate conveyor. The coal was put into a V-shaped arrangement about 8 inches across at the top and 4 inches across at the bottom. At one time the difficulty had been that the coal held up and would not discharge. Now a slit was made in the V so that it opened out and allowed the coal to discharge. One of these retorts which he had seen recently had a capacity of 12 tons in 24 hours. It was 30 feet long and one yard across. Another retort which had not been mentioned was Lamplough's, in which, instead of using an inert gas for heating the coal, superheated steam was used; but he was not certain that, as no external heat was used, this system would be a commercial success. In this country we required large quantities of benzenoid hydrocarbons, which could not be obtained from low temperature carbonisation, and therefore we must depend on gasworks for them. At the present moment the navy needed fuel oil and that was why vertical retorts were being used for carbonising cannel coal. He thought that Mr. Evans was very conservative in putting the yield of tar at 15 gallons, because coal containing about 26% of volatile matter would give at least 20 galls. of tar provided the plant was working properly, whilst in certain cannels he had obtained as much as 80 gallons of tar although only a portion of it could be used for fuel oil. About 30 of the 80 gallons would be suitable for fuel oil, and there would be up to 10% spirit and

small quantities of oil which could be used for lubricating purposes. Reference had been made to the Barnsley plant, which was called a low temperature plant, but if benzenoid hydrocarbons were wanted, why not start at a high temperature? He thought that the process of working in stages would give an infinite amount of trouble and quickly block up the tops of the retorts with carbon. He had made some experiments in cracking oils in this way, and although it was possible to obtain benzenoid hydrocarbons, the yield was very poor and the apparatus was soon blocked up with carbon.

Mr. W. THOMSON, referring to the problem of smoke abatement in large towns, said that it would pay to charge very high prices for a smokeless domestic fuel. Was it possible to take, say, 500 cub. ft. of gas out in the ordinary way from the coal and leave a coke which could be used for domestic purposes?

The PRESIDENT said it was true, as Dr. Armstrong had said, that low temperature carbonisation was approached by most people with considerable prejudice. As an old coke maker in the days of the Beehive oven, he had more than once sacked a workman for producing too large a quantity of black ends in his oven. These old prejudices were really difficult to overcome. The question of the smaller non-caking coal had been referred to. In addition to the small that was brought out of the mine, there was an immense amount of small coal left behind in the mine. He had seen mines in which they loaded the coal with 1½-inch forks, and left everything less than 1½-inch in the mine. In this way an enormous quantity of exceedingly valuable fuel was wasted. The authorities were afraid of the powerful coal miners' union and dared not tell the coal miner to load up everything that was underground. The result was that millions of tons of valuable fuel were left underground and wasted to the nation. This material would be exceedingly well adapted to low temperature processes. With regard to subsidence affecting plant, whenever a coal mine was laid out a large block of coal, which the miner called the shaft pillar, was left unwrought, and all the plant and buildings that were required for working the colliery were erected on that pillar, which was large enough to prevent any risk of surface damage. He could hardly conceive any rational engineer putting his coke ovens anywhere else than within the area protected in this way, and any structure of that kind supported on that shaft pillar was absolutely safe.

Mr. EVANS, in reply, said that the bulk and friable character of the low temperature coke were the crux of the whole question. What was being attempted now was to standardise the product that entered the retort. If coal were carbonised in a tube at a low temperature a structure was obtained which showed a central hole in a series of rings fairly closely compressed at the outside and gradually decreasing in density towards the centre. By a suitable preliminary treatment it was possible to get a solid block right through the mass without any hollow centre. With regard to the more recent developments mentioned by Dr. Perkin, he agreed that the Pringle-Richards and the Tarless Fuel Company's processes gave good results. In many respects the fuel was non-friable, and the only point was whether these processes would work on a large scale. With regard to the President's remarks concerning the shaft pillar, he was thinking of existing conditions at his own collieries where practically the whole shaft pillar was occupied by buildings. There was very little space left on the pillar for a low temperature plant, and he had no doubt that some of the older collieries in the country were in the same position.

NOTES ON THE COMMERCIAL FRACTIONAL SEPARATION OF BENZENE, TOLUENE, AND XYLENES.

BY T. HOWARD BUTLER, PH.D., M.Sc.,
AND F. J. W. POPHAM.

It is beyond the scope of this paper to describe the various plants available for the separation of coal-tar hydrocarbons; it is sufficient to say that efficient plant of British manufacture is now obtainable. The following notes on some of the factors that make for efficiency in working such apparatus may be of interest.

1. *Efficient column* is essential and may be attained by any means so long as intimate contact with vapour and refluxing liquid is obtained.

2. *Efficient dephlegmator*. Dephlegmation plays a most important part in good fractionation. S. Young in his book on "Fractional Distillation" describes dephlegmation as a means for separation brought about by the vapour bubbling through the condensed higher boiling liquid. On the other hand he calls the apparatus on top of a column through which the vapour passes a "constant temperature still head." It is usual now to discard these terms in practice and refer to the former as the fractionating column, and to the latter as the dephlegmator.

By careful regulation of the temperature of the water in the dephlegmator it is possible to increase very materially the efficiency of any plant. This is due largely no doubt to the fact that by this means a larger quantity of condensed liquid is returning down the column, thus affording better contact between vapour and liquid. In regulating any plant it is advisable to work as much as possible by altering the flow of water in the dephlegmator means of open steam, but even then high pressure to the coil in the still.

3. *Constant steam pressure* must be maintained, otherwise regulation of the temperature of still contents is almost impossible. A valve to reduce the pressure of the steam to the minimum usually obtained at any time is a material help in this direction.

4. *A high steam pressure*. A steam pressure sufficiently high to enable the toluene to be distilled off should be available; otherwise a partial vacuum must be put on the plant, which is never so effective. The xylenes may well be distilled over by means of open steam, but even then high pressure steam is preferable.

5. *Tight steam-heating coils*. Should the coils in the still leak even to a very small extent the separation will be entirely upset, and under these conditions it is often impossible to obtain pure products.

6. *Efficient water supply to dephlegmator* requires careful supervision. A works supplied with hard water will soon lose efficiency owing to the fact that the dephlegmator becomes badly scaled; in these cases a water-softening plant is necessary.

7. *Protection of column from external changes of temperature*. In plants put up in the open the columns must be protected against wind and rain, otherwise irregularity in speed of running will result.

The quality of the crude benzol available to the refiner varies very largely. The average, taken from a great number of consignments of "60/65 benzol" from producers, all of which have come to the knowledge of the authors, may be taken as:—

	Average.	Maximum.	Minimum.
	%	%	%
Benzene	45.0	61.1	34.7
Toluene	14.2	19.1	7.7
Paraffins	3.3	9.4	Nil
Xylenes	10.3	20.4	6.7
Heavy naphtha ...	7.3	16.0	4.0
Creosote	13.2	18.0	7.8
Loss on washing ...	6.7	10.0	5.2

The crude benzol is first washed with a dilute solution of sulphuric acid (sp. gr. 1.3), then with about 2% by volume of stronger acid (sp. gr. 1.8), and after washing with water it is agitated with caustic soda solution of sp. gr. about 1.1. For the fractions to be distilled after the crude benzol it is not necessary to wash with dilute acid, but greater care must be taken to wash more efficiently with strong acid and enough be used to free the material from nearly all the impurities.

The loss on washing is a very serious item in the cost of manufacture, and may rise in some cases to 10%. A crude benzol obtained by stripping gas shows a very much higher loss on washing than one from coal tar.

The acid tar obtained from the concentrated acid wash has been a great source of trouble to refiners. The free acid may be effectively extracted by washing with hot water and used in the manufacture of ammonium sulphate. The pitchy residue so obtained must then be disposed of in some manner that will satisfy the requirements of a factory inspector.

The practice followed in distilling for pure benzene and toluene will necessarily vary with different distillers and with different types of plant. Generally speaking, however, the crude benzol is run and preliminary fractions separated. Although with the present forms of column it is possible to separate pure products direct from the crude material, the time occupied in eliminating intermediates is so large and the washing difficulties are so important, that greater economy is obtained by running stills in pairs, one working crude and the other working intermediates for pure products.

The preliminary fractions from the crude are:—(a) Standard benzol, (b) light toluol, (c) crude toluene, (d) crude xylene. The distillation is represented in fig. 1, which shows the main features.

Fractionation of Crude Benzol. Preliminary Separation.

FIG. 1.

The variation in the rate of working will be noted; this rate is increased so long as the distillate is uniform in quality, and is decreased during the passage from one fraction to another. This will

be more apparent in the subsequent figures. The dotted part of the curve represents the distillation converted to normal pressure, the actual distillation under reduced pressure being shown by the solid line.

Fraction (a) consists of benzene and toluene and contains 90–95% benzene. It is fractionated for pure benzene and a yield of 65% is obtained on the first run. Results are indicated in fig. 2, the

Fractionation of Standard Benzol.

FIG. 2.

noticeable feature being the slow rate of distillation until the temperature at the outlet of the dephlegmator reaches a constant value; at this stage the rate can be increased and maintained until the temperature rises, when it is advisable to stop the distillation and recharge on the residue. The temperature of the dephlegmator water during this period is about 42° C., which ensures a good return to the column.

Fraction (b) consists of about 50% of benzene and 50% of toluene, no xylene being present. The working of this is shown in fig. 3. The

Fractionation of Light Toluol.

FIG. 3.

treatment of this fraction indicates perhaps more than any other the efficiency of the modern column. Both pure benzene and pure toluene are obtained in one distillation from the mixture. As the temperature rises after the separation of the pure benzene the rate is decreased, and is increased again when the temperature becomes constant on the pure toluene fraction. The dephlegmator water temperature is maintained at about 42° C. on the benzene fraction and allowed to rise slowly during the distillation of the intermediate until it reaches about 100° C. during the working of the toluene.

Fraction (c) consists of benzene, toluene, and xylene, the toluene content being 75%. The fractionation of this is indicated in fig. 4.

Fractionation of Crude Toluene.

FIG. 4.

Fraction (d) consists of toluene, xylenes, and higher homologues, and is the most difficult fraction to deal with. It will be noted from the curve (see fig. 5) that a comparatively high percentage of heavy toluol is produced and is returned for reworking. When working for solvent naphtha (a mixture of xylenes and higher homologues) the use of vacuum or even of open steam at the end is advantageous, but should be avoided if possible when working for xylenes.

Economy in working can be obtained by observing a definite rotation. It has already been pointed out that the distillation of standard benzol is stopped when the temperature rises after the separation of the pure benzene. After successively working two or three charges in this manner the

Fractionation of Crude Xylene.

FIG. 5.

combined residues have accumulated toluene, and the still may then be charged with light toluol, to be followed by crude toluene. This rotation avoids unnecessary working of intermediate, thus saving both time and steam.

The rates indicated by the curves will necessarily vary with the plant and must be determined for each plant, but they indicate what has been done and show a marked improvement on the practice which obtained previous to the war.

Another point of note is the difference between the separation of benzene from benzene-toluene mixtures, and of toluene from toluene-xylene mixtures. From experiments made by the authors, working on pure compounds in the laboratory, it would

appear that no such difficulty should exist, that is to say, there are no properties inherent in the three hydrocarbons, such as the formation of constant boiling mixtures, which would cause this difficulty. The cause must therefore lie in the plant, probably in the dephlegmation, and might possibly be overcome by the use of salt solution or oil as a dephlegmating medium.

In conclusion, it may be of interest to record differences in the working of paraffinoid crude benzols and those free from paraffin. When dealing with such benzols, in addition to greater care being necessary in the washing process, involving greater loss, a further difficulty is observed in the fractionation. When working for standard benzene it is necessary to "sweat off" the fore-runnings slowly in order to prevent a high paraffin content in the benzene, and to reduce correspondingly the rate on the intermediates when working toluene from crude toluene.

It is very noticeable that in the case of products free from paraffin the "cuts" for pure benzene and toluene are clear and definite, whilst in the case of paraffinoid products a larger percentage of the distillate has to be rejected both at the beginning and end of the pure fraction, although the paraffin content is as low as 0.5%. For instance, fig. 2 shows that when the temperature reaches 78° C. pure benzene can be at once separated and the separation continued until the temperature rises. In the case of a paraffinoid product as much as 10% at the beginning and 5% at the end has to be rejected. The authors attribute this difficulty to the formation of constant-boiling mixtures of the aromatic hydrocarbons and the paraffins; some such mixtures are known, that of benzene and normal hexane being typical.

Another feature in the working of the paraffinoid benzols is the formation of a deposit on the coil in the still, which reduces the heating capacity to a detrimental degree. More thorough washing of the benzol does not prevent this. The nature of the deposit cannot easily be ascertained, because it is rapidly decomposed to a highly carbonaceous compound of indefinite composition.

Frequent cleaning of the still is necessary to maintain the conditions required for successful working.

THE PROSPECTS OF FOUNDING A POTASH INDUSTRY IN THIS COUNTRY.

BY KENNETH M. CHANCE, M.A.

I have already indicated* the lines upon which potash can be recovered in this country in large quantities and at low cost, and I will endeavour in this paper to give some account of the work which has actually been done to lay the foundations of an industry which, if properly developed, should render this country self-supporting not only in those potash compounds such as commercial chloride, carbonate, and caustic which are required in large quantities as raw materials for agriculture and other important industries, but also in those finer chemicals such as those quoted above refined to a condition of chemical purity and the permanganate, ferri-cyanide, and other salts of potassium of which the manufacture in the past has been practically, if not completely, confined to Germany.

Blast furnaces—preliminary investigations.

In the autumn of 1914 the Halberg-Beth plant installed by Fraser and Chalmers, Ltd., at the works of the North Lincolnshire Iron Co., Ltd., for the

* See two papers read at Middlesbrough on January 15th, 1918 "The Cleaning of Blast Furnace Gas for Boilers and Stoves," by A. Lennox Leigh, and "The Commercial Aspect of the Recovery of Potash in the Manufacture of Pig Iron," by Kenneth M. Chance.

purpose of cleaning their blast furnace gases, came into operation. A sample of the dust recovered from the gas was found to contain considerable quantities of potash and of cyanide, and an advertisement was inserted in the technical press offering quantities of this dust for sale. The attention of the British Cyanides Co., Ltd., was attracted to this advertisement and a preliminary examination of the dust led that company to suggest a working arrangement by which a joint investigation should be made by them with the North Lincolnshire Iron Co., Ltd., into the possibilities of producing the dust and working it up into commercial products. This suggestion was accepted and all was ready to commence before the close of 1914, but owing to delay due to alterations in the cleaning plant, it was not until April, 1915, that deliveries of the recovered dust could be sent to the factory of the British Cyanides Co. at Oldbury. This dust was found to contain much less soluble matter (including both potash and cyanide) than the original samples, and upon investigation into the cause it was discovered that the pump used to spray the gases with water in the pre-coolers had originally been out of order but had been put right in the course of these alterations, so that a great deal of the soluble potash was now being taken out of the gas in this preliminary cooling operation and carried away in very weak solution in the cooling water.

Installation and operation of dry cooling plant.

The next step was to introduce some method of cooling the gas without the direct application of water, and for this purpose a Green's economiser was ordered and installed.

This plant came into operation in the early days of 1916 and the next three months were spent in overcoming the usual mechanical troubles inseparable from starting up all new plants, in the course of which it was found that upon the temperature of the water entering the economiser depends to a large extent its smooth working, and it was better to let the cold water meet the hot gases and not cold gases. At the same time experience had been gained in sampling and measuring the gas and in operating the Halberg-Beth plant itself, while at Oldbury the problem of producing potassium carbonate of great purity from the recovered dust had, after several failures, been solved.

Analysis of dust.

The following is the analysis of a typical sample of dust derived from the Halberg-Beth plant at Scunthorpe in the early months of 1916, when the economiser plant was in operation:—Soluble in water: 5.58% KCN, 14.66% K_2CO_3 , 23.23% $KHCO_3$, trace KSCN, 1.13% K_2SO_4 , 3.66% $KHCO_3$, 10.90% KCl, 3.97% Na_2CO_3 , 0.48% $Fe(CN)_2$, 0.36% Zn and Pb as sulphides; soluble in hydrochloric acid: 11.68% Fe_2O_3 , 2.23% ZnS, 10.39% $CaCO_3$, 1.05% MgO, also 8.91% SiO_2 and 2.18% carbon.

It may be of interest at this stage to give some figures of the alkali and chlorides contained in the dust recovered from the plant during the months which led to prematurely optimistic views being formed. The total alkali and chloride are expressed in terms of potash, the actual proportion of soda to potash being found constant at about 10 to 90; i.e., from the figures given below about 10% should be deducted to obtain the actual percentage of potash in the form of carbonate and chloride.

In May (before the discovery of the effect of the sprays in carrying away the soluble salts, especially the very soluble carbonate) the percentage of alkali as K_2CO_3 and of chloride as KCl were each in the neighbourhood of 22% of the dust.

The following table gives the corresponding figures from July, 1915, to February, 1916:—

	1915					Dec., 1915- Jan., 1916.	1916
	July	Aug.	Sept.	Oct.	Nov.		Feb.
Alkali as K_2CO_3	42.31	42.07	43.66	41.85	38.02	40.02	37.85
Chlorides as KCl	15.36	15.28	14.14	14.95	15.94	14.17	11.86

By the end of March, 1916, it was thought that all difficulties had been overcome, and a report was sent to the Director of Optical Munitions giving details of this new source of production of pure potassium carbonate, which had then already been supplied for some months to the largest maker of optical glass in the country.

Hardly had that report reached its destination, however, when the quantity of soluble potash in the dust began seriously to decline. The average test for March showed 30.29% alkali as K_2CO_3 and 12.07% chloride as KCl, for April 26.29% and 16.22%, and for May 24.27% and 17.42% respectively, while, at the same time, the proportion of soda to potash in that alkali had doubled, and the proportion of chloride to alkali, which had been nearly constant at 3:8 rose until it was 2:3.

An immediate investigation into the cause of the decline was set on foot, which took the form of daily tests of the gas from both of the furnaces then in blast and a comparison of these tests with the analysis of the slags drawn from those furnaces during the same period and with the proportion of coke to ore charged into the furnaces. It was clearly demonstrated by this investigation that the potash charged into the furnace and issuing from it both in the gas and in the slag was sufficient to produce upwards of 200 lb. as K_2CO_3 , together with 25 to 30 lb. as KCl per million cubic feet of gas, so the next step taken was to make a careful analysis of all the available information and to hold a conference on the possibility of carrying out experiments in a blast furnace without detriment to the quantity or quality of the iron produced.

Numerous suggestions were considered, including that of introducing into the furnace some basic material which would flux at comparatively low temperatures, but it was decided to commence by determining the effect of increasing the proportion of lime to silica in the charge. Mr. Leigh pointed out that this would inevitably necessitate an increase of temperature in the furnace, and the results were carefully charted in order that the relative influence of increased base and increased temperature might be determined.

These preliminary experiments failed to provide any information that could be regarded as conclusive, but they indicated that the temperature of the furnace had some influence upon the quantity of potash volatilised into the gas in the form of carbonate.

Mr. Leigh thereupon undertook to carry out a series of short experiments whereby the temperature of the furnaces should be raised for periods of two or three days at a time, and daily samples of the gas, dust, and slag from those furnaces were analysed for their potash contents.

Increased production of potassium carbonate.

These experiments were commenced on August 5th, 1916, and their issue was hardly ever in doubt, as will be seen from fig. 1. Daily tests of the gas from both furnaces had been taken from the middle of March to that date, and the maximum weekly average of those tests had shown less than 60 lb. K_2CO_3 in the gas and had fallen as low as 23 lb. per million cubic feet during the week ending April 22nd, the average for the week ending

tests from the same furnaces for the week ending August 6th and the period in question:—

Lb. Alkali expressed as K_2CO_3 per million cubic feet.

Period.	No. 2 Furnace.			No. 4 Furnace.		
	Highest.	Lowest.	Average.	Highest.	Lowest.	Average.
Aug. 1-6	66.1	30.5	48.6	38.3	12.4	21.3
Oct. 1-18	122.0	81.0	81.4	123.0	63.0	91.6

After October 18th the furnaces from which these results were recorded resumed normal working and the alkali in the gas (expressed as K_2CO_3) rapidly fell to the normal figure of about 40 lb. per million cubic feet. In November the experiment was repeated, and the alkali again raised to an average of more than 100 lb. for a week towards the end of that month, with a high record of 140 lb. on November 20th from one furnace. Similar measures were then taken in a furnace at the Scunthorpe works of John Lysaght, Ltd., and although no records so high as these were obtained, the alkali in the gas was increased to an even greater extent in proportion to the normal amount found in the gas at these works, which is greatly below that at the North Lincolnshire Iron Company's works.

These figures are open to criticism in that they are unaccompanied by accurate records of the temperature of the furnaces and of the actual weights of lime and silica charged into them. The conditions under which we were working rendered it impossible to obtain such records. The blast furnaces were not fitted and could not be fitted with pyrometers. In ordinary blast furnace practice it is impossible to analyse every charge for lime and silica and to weigh the contents of each with that minute accuracy which would be necessary for such records. Above all, these experiments were carried out in time of war and the labour required for such purposes was not available.

Although, therefore, there is a mass of figures available in the form of daily tests and records, which can be made public if its publication can serve any useful purpose, the information provided is not conclusive. Indeed it is probable that no really conclusive proof of the relative influence of base and temperature upon the volatilisation of potash in the form of carbonate from a blast furnace can be tabulated unless a blast furnace is specifically designed and constructed for a thorough research into this problem, although one further experiment which we carried out may possibly have some bearing upon it.

Soda ash was added to the furnace regularly in suitable quantities over a period of three or four days to the extent of five tons. The effect upon the production of potassium carbonate was at the best inconsiderable—indeed it is questionable whether it had any effect at all—and was in marked contrast to the immediate effect resulting from the addition of salt to the blast furnace of which some account is given below.

Perhaps the strongest evidence as to the influence of the combination of high temperature with high basicity in the slag is furnished by an analysis of the gas and slag produced in the manufacture of ferro-manganese, where both the proportion of lime to silica and the temperature at which the furnace is operated are considerably higher than in normal blast furnace practice. In this case the slag contains the merest trace of the potash charged into the furnace, practically the whole of which is volatilised into the gas in the form of carbonate, cyanide, and chloride.

It is therefore permissible to assume that if the same methods could be applied to the production

of pig iron the same results would be obtained and potassium carbonate would be readily available in large quantities, but unfortunately the cost of operating a blast furnace in this manner is so great as to be prohibitive for the manufacture of pig iron, and some other method of volatilising the potash in the ordinary blast furnace had, for this reason, to be found.

A wider demand for potash.

Up to the close of 1916 the requirements of potash that had made themselves urgently felt were all for potash in the form of carbonate, especially for making optical glass, and its production in that form had therefore been our sole objective under the auspices of the Controller of Optical Munitions, Mr. Esslemont. About that time, however, the vital need for potash in a form suitable for use on the land was made known to Mr. Esslemont, who therefore asked me to draw up a scheme for meeting those demands, thus placing the problem of quantitative and cheap production in the forefront. The first suggestion was obviously the collection and distribution of the dust drawn from the stoves and boilers at blast furnace works, because the process of combustion removes all impurities that are harmful to agriculture from this dust, which consists of carbon, lime, and potash. But at the best, the collection and distribution of this dust could only be regarded as a temporary expedient and partial stop-gap and could not form the basis of an industry which would render this country self-supporting in providing potash at reasonable prices, because the quantities available are insufficient and the proportion of potash in the dust too low. It was therefore necessary to find some other source of supply.

Consideration of other methods of production.

I have already narrated how at times the production of dust from the Halberg-Beth plant of the North Lincolnshire Iron Co., Ltd., had fallen off either in quantity or in quality to such an extent as made it appear extremely doubtful whether permanent supplies of potash at prices which could compete with German production after the war could ever be collected as a by-product of the manufacture of pig iron. In the meantime, the British Cyanides Co., Ltd., was endeavouring to produce some of those refined potassium compounds the manufacture of which either had never yet been achieved in this country, or had been killed by German competition, and it had become a matter of vital urgency to that company, before the national need was fully recognised, that its supplies of raw material should be secured. Problems therefore such as the recovery of potash from felspar, from alunite, or as a by-product of the manufacture of cement, had all been carefully considered in the early days of the war by the directors and staff of that company.

It may not be out of place to give the reasons which led us in those early days to continue to devote time and money to the blast furnace problem in preference to any of these others, although the British Cyanides Co. had already experienced to the full in the recovery of cyanide from coal gas the difficulties of persuading a large body of individual manufacturers of the benefits to be derived from the central collection and refining of a by-product of their ordinary manufacture, and we were not therefore in any way attracted by the prospect of having to repeat this propaganda work in the recovery of potash as a by-product of pig iron manufacture.

The recovery of potash in a gas-cleaning plant at a blast furnace has one enormous advantage over all other native sources of supply in that the

value of the main product of that plant, namely clean gas, is in itself sufficiently great to provide a handsome remuneration for the capital outlay involved in erecting it and the cost of its operation, so that the cost of recovering potash already in the gas in the form of dust is *nil*. The second consideration is that the main items of cost in volatilising potash from an ore in which it is present in insoluble form, namely cost of raw material, labour, and fuel, are, in the case of a blast furnace, already incurred and reckoned as items of cost in the manufacture of the main product, pig iron. The third consideration is that, to the best of my knowledge, there is no bed of felspar or similar ore in this country which can compare in magnitude or convenience of situation with the soluble potash deposits in Stassfurt and Alsace, while the cost of producing soluble potash from such insoluble ores must inevitably compare unfavourably with that of refining the soluble deposits above referred to.

The development of the salt process.

In fig. 1 it will be seen that there is a straight line representing lb. KCl per million cubic feet of gas, which remained practically constant at about 30 lb. throughout the wide variation of K_2CO_3 recorded in the course of these experiments.

Investigations at the works of John Lysaght, Ltd., extended the range of variation in the alkali contents of the gas down to zero, but the quantity of KCl remained practically unchanged.

There emerged, therefore, the notable fact that while the alkali in the gas varied from 0 to 140 lb. per million cubic feet, the volatile chloride remained practically constant. The natural inference was that the chlorides in the furnace charge were practically constant and were all volatilised into the gas, so that if additional chlorides were artificially fed into the furnace they would combine in the zone of reaction with those bases having the most volatile chlorides. It followed that as the most readily volatilised of all the chlorides is that of potassium a large proportion of the potash charged into the furnace would be volatilised into the gas in that form.

This theory had already met with some confirmation from an examination of the proportions of potash to soda in the total chlorides already found in the gas, which varied from 85% to 90% of potash and 10% to 15% of soda, whereas the proportions of potash and soda in the furnace charge were approximately equal.

The North Lincolnshire Iron Co., Ltd., thereupon consented to try the experiment of adding salt to one of their furnaces in sufficient quantity to volatilise the whole of the potash in the furnace. This was done in February, 1917, and the success was instantaneous, the chlorides in the gas rising from about 30 lb. per million cubic feet to upwards of 200 lb. expressed as KCl, while the proportion of potash to soda in the total chlorides was not decreased but remained at about 9 to 1 and the alkali in the gas was unaffected. The actual potash in the gas as alkalis and chlorides combined was therefore raised from about 60 lb. to upwards of 200 lb. per million cubic feet of gas.

The use of salt has been repeated in several blast furnaces in other parts of the country since that time and, while the quantity of potash volatilised naturally varies with the quantity charged into the furnace, in no case has the addition of salt failed to more than double the quantity of potash found in the gas, while in others it has trebled or quadrupled it. (See Eng. Pat. 112,338 of 1917; this J., 1918, 88 A.)

The extended use of salt in blast furnaces has up to the present disclosed, so far as I am aware, no adverse results as regards the manufacture of pig iron.

The cost of producing potash by the salt process.

It is obviously impossible to give more information on this subject than can be deduced by the application of technical knowledge to the main facts regarding the process which have now been made public, but some general deductions may be drawn. The cost of cleaning the gas must be debited to the cost of the pig iron, and the cost of the raw material at the blast furnace works is therefore limited to the cost of salt, of which about three tons is required for the production of four tons of potash in the dust. For purposes of comparison with pre-war figures, £1 per ton of salt delivered to the blast furnace works, or 15s. per ton of potash, should be ample allowance. The next item of cost is that of carriage in bulk to a central factory, and for this 5s. per ton of dust, or say 12s. per ton of potash, should suffice. The cost of potash in the raw material delivered to the central factory may therefore be estimated at 27s. (say 30s.) per ton.

From this stage the cost of production of potassium chloride differs only from that of producing sodium chloride in the following particulars:—1. Lixiviation of the dust as compared with pumping the brine. 2. Elimination of impurities. 3. Scale of operations. Of these items of cost the last is by far the most important, and it is only possible to draw any comparison between the cost of production of these two chemicals if the scale of operation is comparable. An output of 500 tons per week, which is the figure that I have given as the minimum size for each central factory, would be considered small for a salt works, but it is a scale of production sufficiently large to justify a comparison of this nature, and at the same time the distribution of the blast furnace industry in this country is such as to justify the anticipation that where the use of gas cleaning plants is general, central factories on this scale can be erected at suitable points so that the cost of carriage of the dust to them will not on the average exceed the figure of 5s. per ton indicated above.

We have therefore the following information available as to the cost of production of potassium chloride by this process:—(a) Cost of raw material delivered to central factory, say 30s. per ton KCl. (b) Cost of refining; comparable to (say for example double or treble) the cost of production of common salt. (c) Cost of bagging and distribution. (d) Profit to the blast furnace owner and to the refiner.

Two points arise from this:—The first that the process of manufacture is thus strictly comparable to that of any heavy chemical, and therefore its cost will inevitably depend very largely upon the scale upon which that manufacture is conducted. The second that by the use of suitable quantities of salt in blast furnaces, coupled with the installation of efficient gas cleaning plants, a raw material is recovered as a by-product of the pig iron industry from which the manufacture of potassium chloride can be carried out on a sufficient scale to meet the requirements of this country and at a price which, on a pre-war basis of cost, is less than the lowest figure at which German potassium chloride has ever yet been marketed in this country, namely £8 per ton, after providing a margin of profit to the blast furnace owner and to the refiner.

At this point I should like to pay tribute to the large part taken by the directors and staff of the North Lincolnshire Iron Company, Ltd., and especially by Mr. Leigh, in this work. I am only now beginning to realise the difficulties in which Mr. Leigh must frequently have found himself in meeting suggestions which were based upon experience of large scale experimental work on furnaces designed for a totally different purpose and from lack of experience of blast furnaces. The credit of

meeting and overcoming these difficulties is due to Mr. Leigh, ably seconded by Mr. Langdale and Mr. Parker. Valuable assistance was rendered by Mr. Williams, of John Lysaght, Ltd., in confirming our results. The actual research work on the spot was entrusted to Mr. Dingley, under the supervision of Mr. Rossiter, Chief Chemist to the British Cyanides Co., Ltd., who was responsible for the control of this work both at Oldbury and at Seunthorpe.

Two other sources of by-product potash.

Apart from the blast furnace industry there are two other industries in this country from which potash may be recovered as a by-product, namely, the manufacture of cement and the washing of raw wool.

Cement. By use of salt in the cement kiln, whether in the crystalline form or as sea water, there is ample evidence both in this country and from the United States to show that potash in considerable quantities is volatilised into the waste gases from the kiln, and in the latter country particulars have been published of plants that have been erected for the recovery of the dust from these gases, the lixiviation of the potash therefrom and its crystallisation from concentrated solutions.

In both countries the greatest difficulty has proved to be the construction of cheap and efficient plant for extracting the potash from the gas. Various methods of washing the gas have been tried, and the removal of the dust by electrical precipitation and in a bag plant of the Halberg-Beth type has also been attempted.

According to one authority a combination of electrical precipitation and the collection of the dust in the form of a slurry has been found successful in producing potash at a profit in the abnormal conditions that exist at the present time, but in looking to the future it must be remembered that the gas from a cement kiln has no value beyond its potash contents, while the value of blast furnace gas is enormously increased by the removal of the dust from it. The former industry thus labours under the disadvantage of having to debit the whole cost of the cleaning plant to the potash recovered by it, while that cost is borne by the increased value of the gas from a blast furnace, and, therefore, unless some counter-balancing advantage can be discovered and utilised, the cost of recovering potash must always be greater from a cement kiln than it is from a blast furnace. It is probable that this compensation will be found in the condition of the dust itself, which contains the potash in a form in which, owing to its being recovered from gas which has been burnt, and to the harmful impurities, such as carbonates and cyanides, having been thereby destroyed, it is suitable for direct application to the land. The best line of development for the recovery of potash as a by-product in the manufacture of cement would therefore appear to lie in the direction of the recovery of the dust in the dry state for direct sale as a fertiliser containing about 25 to 30% of potash as K_2O , in the form of the chloride and sulphate, with lime as the preponderating impurity.

Suint. The third source of by-product potash in this country is the wool-combing industry which is centred in Bradford.

The method of washing the raw wool generally adopted is to scour it in hot water with alkali and soap in three or four different vessels, thereby removing the potash in very weak solution contaminated with large quantities of fatty matter and other impurities in addition to the soap and alkali. In many cases the fatty matter is now recovered from these solutions, but the liquors are run to waste as having no value.

By a preliminary washing of the wool in cold water, the potash can be recovered from it as carbonate in a solution which is contaminated with a small proportion of the natural fats of the wool. This practice appears to have been more widely adopted in the past than it is now, because at a time when both potash and soda were more costly than they became during the latter part of the last century, it was a profitable undertaking to recover the potash in this form, concentrate it, and thus provide the alkali for scouring the wool in the second stage.

Owing, however, to purely physical difficulties of concentration, due to the fatty contamination of the weak potash solutions, the recovered potash has always taken the form of an impure mixture of carbonate and sulphate, and as such has been of little commercial value, while the fats present in the weak solution have been destroyed in the process of concentration.

If these difficulties can be overcome there is no doubt that potassium carbonate of great purity can be recovered from the preliminary washing of wool with cold water, and the fats rendered of value in the form of gas and oils.

The work that has been accomplished.

The salt process is at work at more than one blast furnace works in this country, cleaning plants are extracting the potash from the gas at those works in the form of dust, the first factory for treating the dust has been erected and is now producing potassium chloride at the rate of some fifty tons per week. There are in addition cleaning plants in course of erection at other blast furnace works, and the factory referred to, which is situated at Oldbury, is designed for a total output of from 400 to 500 tons of potassium chloride per week, and as supplies of raw material become available, will be brought up to that scale of production.

Arrangements have been entered into with one of the leading chemical companies engaged in electrolytic work for the manufacture of caustic potash in bulk from the chloride by electrolysis, and in a short time caustic potash from this native source will be available both in the commercial form and in the pure state, and at the same time chloride, refined for druggists' use, will also be available.

The problems connected with the manufacture of the following salts of potassium in their pure state have been overcome, and they are all now being produced on a scale sufficient to meet the essential needs of the country in time of war:—

Potassium carbonate testing upwards of 99% K_2CO_3 .

Potassium bicarbonate testing upwards of 99.5% $KHCO_3$.

Potassium ferricyanide testing upwards of 99.8% $K_3Fe(CN)_6$.

Potassium permanganate testing upwards of 99.8% $KMnO_4$.

Admittedly at present prices are high and the ordinary consumer who cannot make out a case for war necessity has to go short, but now that the initial difficulties of manufacture have been overcome, and alternative methods have been worked out to permit of advantage being taken of potash in the form either of the chloride or the carbonate, whichever be the more readily available, or the cheaper, and now that arrangements have been made for the mother liquors from one process to be used as the raw material for another, a gradual improvement, both in the quantities of these chemicals that are available and in the price at which they can be purchased in the open market, may be confidently anticipated.

Some indication as to the magnitude of the difficulties which had to be overcome may perhaps be worth mentioning. In the first place the problem

of producing potassium carbonate suitable for use in the manufacture of optical glass and also for druggists' use from the impure blue dust was especially difficult on account of the crude nature of the raw material and the exceptionally high standard of purity demanded in the finished article, and three experimental works-scale plants were erected and discarded within less than six months before a method was evolved for the manufacture of a product which has fully satisfied the exacting requirements of these two industries.

In the manufacture of ferricyanide we soon found that nothing short of chemical purity would be of any real value, and that high standard was only attained by laborious experiment on the elimination of impurities. In the case of permanganate, a plant was laid down for its manufacture by the text-book method of fusing caustic potash with manganese dioxide and oxidising the soluble manganate with carbon dioxide on a scale of production which in the early stages was regarded as ample for all possible requirements. Those possible requirements were, however, doubled, then quadrupled, and have recently been multiplied by eight, so that a less cumbersome method had to be devised and installed at short notice without jeopardising the scanty supply of potash that was available in the form of carbonate, or the rate of production of permanganate that had already been reached. At the present time the only form of potash used in the manufacture of both potassium permanganate and ferricyanide is the chloride.

In working out these technical problems, erecting the factory of the Potash Company to treat the blue dust, and remodelling one of the factories of the Cyanides Company for the production of pure potassium salts, I was able to employ the organisation built up by the latter company prior to the war, and I wish to mention the invaluable assistance afforded me in this work by Messrs. A. E. Doherty, Manager, J. A. Fullagar, Chief Engineer, and E. C. Rossiter, Chief Chemist of that company. Developments of this nature in time of war are attended with difficulties infinitely greater than in normal times, but such difficulties only serve as spurs for further effort on the part of these men and the staff and workmen under them.

The work now in progress.

Although the arrangements which have already been made are sufficient to ensure the production of potash in this country to an extent which before the autumn of this year will meet the requirements of the country for all essential purposes in time of war, other than explosives and agriculture, the needs of agriculture are so great and, in these times, so paramount, that every ton of potash which is used during the next few years in the chemical industry will, in a sense, be decreasing the potential food supplies of this country.

At the same time it is hardly an exaggeration to say that the present output of 50 tons per week of commercial potassium chloride represents but 1% of the potential supplies now going to waste in this country, and the plants now in course of construction will only serve to render available about one twentieth of that waste.

The engineering problem which transcends all others in importance is that of designing a really cheap and thoroughly efficient plant for removing the fine potash fume in the dry state from large volumes of gas both from blast furnace and cement kiln. Experimental work on the lines which have proved successful in solving the problems that have already been described is now being actively pressed forward, and as soon as these preliminary experiments have been taken sufficiently far to indicate the correct design for a unit capable of handling one million cubic feet of gas per hour, trial plants

on that scale will be constructed and erected at blast furnace and cement works where facilities for such trials have been generously offered.

The qualifications essential to success in such a plant are that it shall be simple to construct, erect, and operate, that its construction shall not make undue inroads upon materials that are difficult to obtain, that its erection shall not throw heavy demands upon skilled labour, its capital cost (apart from mains and connections) shall not exceed £5000 for each unit of that capacity at the inflated prices current to-day, and its operating cost shall not, under existing conditions, amount to $\frac{1}{2}$ d. per 1000 cubic feet of gas.

The plant must be practically fool-proof when handling gas under the wide variations of temperature and vapour density which are inseparable from ordinary blast furnace practice and it must be capable of being constructed and erected within the limits of time imposed by the acquisition and erection of the mains and connections required to bring it into operation.

Those are briefly the objectives which have been laid down, and until they are reached the foundations of a potash industry in this country will not have been so securely laid as to exclude competition from abroad.

The second problem which is now being tackled is the treatment of the suint liquor which is being conveyed in quantity from Bradford to Oldbury for experimental work on a practical scale in the plant which has already proved its suitability for experimental work of this nature, and considerable progress has been made towards its solution.

Conditions essential to success.

When these problems have been solved, as they assuredly will be, the formation of a strong and healthy potash industry will be cleared of the chemical and engineering difficulties which have hitherto compelled this country to pay tribute to Germany for every ton of potash that it consumes.

The combination under one control of all the German potash interests has created one of the most absolute and powerful monopolies that the world has ever known, and we can be very sure that nothing will be left undone to prevent that monopoly being broken.

To bring about a similar combination of interests in this country must inevitably be far more difficult than in Germany because of the widely diverse industries from which these potential supplies of by-product potash must be drawn and because each of these great industries as a whole is composed of a large number of individual firms. In fact, the comparative unimportance of by-product potash to any one of these firms as a source of revenue in the future, when prices are brought down to a normal level, renders it absolutely essential that the plant installed for its recovery shall be cheap of construction and simple in its operation and that the producer shall be able to dispose of the crude product easily and automatically to central refining factories and shall not be burdened with the complications of an intricate process of chemical manufacture.

It is these considerations, no less than those to which I have drawn attention earlier in this paper, which have forced me to the conclusion that the production of potash in this country on a scale and at a cost which will enable German competition to be faced, can only be effected by the unification of all the varied interests involved; and the more deeply that the problem is studied the more clearly does this stand out as the only possible road to success.

DISCUSSION.

Capt. C. J. GOODWIN said that in considering the question of a national potash industry it was important to consider what would be the position

after the war; the only basis of comparison available at present was the pre-war basis, and he hoped it would be possible to show that the industry could be established without the necessity of import restrictions or similar measures. Considerable doubt existed as to the actual cost of potash manufacture in Germany before the war; it had been given on various occasions as between £4 and £6 per ton. Mr. Chance had stated that the cost of gas cleaning should not exceed $\frac{1}{2}d.$ per thousand cub. ft., or 7s. per million cub. ft., and the corresponding quantity of potash recovered, viz. 200 lb., was worth about 15s. If the cost of cleaning the gas materially exceeded that figure the margin of profit would be greatly reduced. A great deal of work had been done in the last few years on the treatment of felspar; the problem was particularly applicable to those parts of the Empire where blast furnaces were perhaps not available and in countries where there was unlimited scope for agricultural development. In that connection the volcanic deposits in Italy, which contained leucite, were of great interest. He also referred to the Ashcroft process, in which such rocks were treated at high temperatures with common salt, with a recovery of about 85% of the potash. He understood that the cost of producing potash by this process was less than the pre-war price of German potash. This and similar processes appeared to be similar in principle to the blast-furnace process described by Mr. Chance, each depending on the reaction between sodium chloride and a potassium compound in the absence of oxygen.

Mr. C. J. WATERBELL said that the possibility of utilizing felspar appeared strongly to those in the West of England, where there were extensive deposits of that mineral.

Dr. E. F. ARMSTRONG emphasised the point which was made throughout the paper, that the whole question was an economic one—that the potash would have to be recovered at a cost which would permit us to compete with natural salts. Mr. Chance appeared to be somewhat apprehensive as to the possibility of getting enough blast furnaces and similar works to purify their gas to produce sufficient raw material for a really large plant for extracting potash. He suggested that it was in matters of this kind that societies like their own and the Association of British Chemical Manufacturers, and ultimately, if necessary, the State, should help. It should be made compulsory that these cleaning plants were attached to blast furnaces, but at the same time it must be made sufficiently profitable for the blast furnace companies to do this. It was frequently said that the manufacturer had no right to make any profits beyond a bare 5%; if that doctrine made headway it would be impossible to establish the potash or any other industry in this country. These very excess profits which were being taken away from blast furnace owners might be usefully employed in wiping off the capital cost of these cleaning plants.

Dr. F. M. PERKIN pointed out that some blast-furnace dusts contained large quantities of iron dust and iron oxide. How would such dusts be treated in the process described by Mr. Chance? He agreed with Dr. Armstrong's remarks about the employment of capital; the great German dye industry was largely built up by wiping out excess capital, and the capitalisation which appeared on the books of the great German dye and chemical firms was very small compared with the actual amount of money that had been spent on the plant.

Mr. C. S. GARLAND said that it must not be expected that blast furnace dust would be obtained for nothing. As in the case of other waste products formerly considered as useless, when it was realised that it was of value the price would certainly rise.

Dr. S. MIALI suggested that a committee might be appointed by the Society, in conjunction with the Association of British Chemical Manufacturers, to confer with Government departments with a view to obtaining the organisation indicated by Mr. Chance.

Mr. PATTERSON pointed out that whilst it was quite true that it would pay the blast-furnace owner to have clean gas, he would not, in order to get clean gas in the ordinary way, go to the same expense as if he were desirous of extracting potash. For instance economisers had to be put in instead of the usual wet-cooling plant, and these were much more expensive than the cooling apparatus in the original Halberg-Beth process. Therefore the blast furnace owner would have to be paid that extra expense. At the present time probably not more than 10 or 15% of the dust produced in blast furnaces was treated. Much of it was deposited in the tubes and the downcomers, and it was only the fine suspended matter that was treated.

Mr. F. SOUTHERDEN asked whether the author could give figures of the cost of recovery of crude dust from the furnace gases and also whether experiments had been tried in the use of this crude dust for fertilising purposes.

The PRESIDENT said that he was possibly one of the earliest to have found potash in blast furnace dust. In 1878, when chemist to some blast furnaces in Nova Scotia, he had analysed the dust from some Siemens-Cowper stoves and found a considerable amount of alkali, especially potash. The fact had been of no importance at that time, but the present significance of the matter had been made evident by Mr. Chance. He thoroughly endorsed the view that the cleaning of dust in some way or other paid for itself. Many years ago he had been concerned in installing in Sweden one of the first blast furnace gas engines; within six months of putting in that engine, the piston rod was worn $\frac{1}{2}$ -inch all round and was very soon useless, owing to the scouring action of the dust in the gas. As long as the old method, still largely used, of burning the gas under boilers was used, very crude cleaning was sufficient, but for use in a gas engine, the most efficient cleaning possible was required, and blast furnace owners had spent very large sums upon efficient cleaners. He agreed with Mr. Patterson that hitherto wet cleaning had been found to be the cheaper, but there was no evidence that that would remain the case. The Cottrell electric process was exceedingly promising. As regards the use of salt in the blast furnace, he wondered whether it would not cut the top bricks a good deal, and it occurred to him that a cheap waste product like calcium chloride might be found equally efficient.

Mr. CHANCE, in reply, said that a large amount of work had been done in America on the Cottrell process, but the capital cost was very high and it certainly did not come within the conditions he had laid down in the paper. The difficulty appeared to be with the extraordinarily fine fume. At first he had thought it would be possible to settle the fume out, but in a test it still floated at the end of a week. If the gas were kept hot it was possible to deposit the fume, but if it were allowed to cool so that the specific gravities of the gas and the fume were approximately the same, it was impossible to remove the fume by settling, and the difficulty with the Cottrell process was that if this very fine fume was to be deposited on the tubes or plates, it was necessary so to lower the velocity of the gas that the size of the plant became enormous and the cost became prohibitive. Also when this fume was once deposited on the plates or tubes the great difficulty at the low

velocities was to prevent it being carried on. That had been overcome in America, he understood, by a double system of plant whereby the gas was passed first over plates or through tubes at a fairly high velocity, and on the way practically all of the heavy dust was recovered and a certain amount of the fume. In the second plant a stream of water trickled over the plates or tubes. The objection to that, however, was that the vapour density of the gas was raised very considerably, and the heating properties were largely reduced; it also resulted in the dew point being lowered, and vapour was deposited. With regard to adding salt to blast furnaces, there had been a good deal of evidence one way and another, but the actual putting in of the salt made no difference except that it increased the quantity of potash. In a paper read at Middlesbrough about 15 or 20 years ago it had been shown that the bricks from an ordinary blast-furnace became so saturated with potash that on the inside they contained from 40 to 50%, and even on the outside wall of the furnace from 5 to 10%. Their experience only went back to January, 1917; one of the furnaces had not shown any sign of deterioration due to the use of salt, nor did he find any objection was raised by blast furnace owners. In reply to Dr. Perkin, iron dust fell out in the downcomers, but it did not reach the cleaning plant, or only in very rare cases. He was not at liberty to give any further details as to costs. In regard to the cost of cleaning referred to by Capt. Goodwin, the figure of $\frac{1}{2}d.$ per unit only referred to cleaning of cement kiln gases. With the Cottrell process 0.05d. or 0.06d. was said to be the cost, and he believed that claim was quite justified, except that he did not know at what rate they reckoned depreciation of plant. One of their present problems was to design a cleaning plant which would get over the difficulties that had been pointed out. The present economiser was too costly. The Green's economiser was made for a steam pressure of anything up to 200 lb., and therefore they were using a plant which was far too costly for the purpose. The difficulty at present was that there was no plant on the market for cleaning gases thoroughly, with the possible exception of the wet cleaning plant, and he did not think that blast furnace owners favoured that type of plant. There were only one or two in use in this country, but it was more commonly used in the United States. For dry cleaning there was no plant on the market except the electric process and the Halberg-Beth plant; both of these used a very large amount of steel and, incidentally, were very costly. With regard to Government assistance, he mentioned that half the shares in the British Potash Company were owned by the Government and they had Government assistance to a very large degree. The suggestion that a committee of the Society should be formed was a most valuable one, and the time might come when it would be of the utmost assistance to the potash industry, but at the present time the trouble was not lack of Government assistance, except perhaps in regard to labour. The chief trouble was that the proper plant was not available.

SOURCES OF LOSS DURING THE MANUFACTURE OF CONCENTRATED AMMONIA LIQUOR.

BY ARTHUR MARSDEN.

Several very instructive papers* have recently appeared in the technical press on the subject of concentrated ammonia liquor, and the object of this paper is to describe the sources of ammonia

loss present when making that product, together with some of the remedies applied, and it is hoped that the suggestions may be productive of further improvements in the efficiency of the process.

The general principles of manufacture are well known and need not be described here. In pre-war plants the method largely used was that of "fixing" all the carbon dioxide and hydrogen sulphide in the liquor by means of lime. This has now been replaced by the process of "decomposing" the liquor, prior to distillation, at a temperature below boiling point, in order to liberate as much of the carbon dioxide and hydrogen sulphide as possible together with the least amount of ammonia. The conditions necessary to effect this end are, in practice, often difficult of attainment and vary in different types of plant.

After leaving the heater or economiser the liquor usually flows direct to a "decomposer" or "desulphuriser" and during its passage down that apparatus the evolution of carbon dioxide and hydrogen sulphide takes place progressively due to rising temperature, until, towards the bottom, the temperature is high enough to liberate ammonia, much of which is absorbed again in passing upwards through the cooler trays. The ammonia passing away with the outlet gases is dealt with in different ways, according to circumstances.

The remarks which follow deal in particular with a plant of the Wilton type, consisting of a combined still, 5 ft. 4 in. internal diameter, and liming vessel, capable of dealing with 26,000 gallons of 7 oz. liquor per 24 hours, together with a 13-tray desulphurising still 5 ft. 4 in. internal diameter; a catch tower to arrest, by means of water, the ammonia driven off from the desulphuriser; an exchange liquor heater; reflux and final condensers, and the usual accessories. The still has 15 trays, including one "liming" and one anti-priming section. Each tray has one rectangular serrated hood running across the centre, and is provided with suitable hand holes for removing the hood. The liming vessel is a circular cast iron vessel 3 ft. 6 in. internal diameter and 7 ft. high. It is fitted with a live-steam distributor at the bottom.

The desulphuriser gases may be dealt with in various ways. In some cases they are returned to the foul-main, but difficulty has been experienced owing to the formation of ammonium carbonate in the pipe conveying the gases. Deposits of naphthalene have also given trouble, especially if light tarry matter entered the desulphuriser with the liquor. In any case complete freedom of the liquor from tarry matter is most desirable. In other cases where a sulphate of ammonia plant is arranged in conjunction with the liquor concentrating plant, the desulphuriser gases are passed directly to the saturator. That method also appears to have objections because, unless the sulphate plant is in operation, apart from the liquor plant, the "bath" needs much attention if the formation of "blue-salt" is to be avoided, also, any naphthalene driven forward is liable to cause a dirty, dark-coloured salt, which can only be remedied with difficulty. The treatment of the gases by means of an acid bath offers, on the other hand, an advantage in the case of liquors containing much pyridine which, being basic in character, is arrested by the acid, whereas when a catch tower fed with water is used, as in the case of the plant here dealt with, much pyridine passing to the purifiers may become very objectionable and render the washing of the gases by oil necessary.

For the purposes of this paper no account has been taken of any losses occurring during the production, storage, or delivery of the crude liquor to the plant, although those phases of what may be termed the "ammonia question" provide much

* Gas J., 140, 412, 554, 603; 141, 395.

material for investigation, and are receiving attention.*

The plant here dealt with was put to work in October, 1917, and worked satisfactorily as far as the quality of the concentrated liquor produced was concerned, which averaged 28.12% NH_3 and 0.45% H_2S by weight, but it soon became evident that considerable losses of ammonia were taking place, the usual works' stocks indicating an efficiency of conversion, from crude to concentrated liquor, in the neighbourhood of 80%. As a result the plant was run under test for 24 hours, maintaining as far as possible the usual conditions of working, but taking careful series of readings and measurements. The figures obtained showed that, of the total ammonia supplied to the plant as crude liquor, 90.1% was obtained as concentrated liquor. This improved result when compared with ordinary working was doubtless due to the increased and constant supervision during the test. The results obtained were as follows:—Average rate of liquor flow to plant, 63.1% of rated capacity. Average steam on still (first tray), 18 lb. per sq. in. Temperature of gases at outlet of desulphuriser 68.1° C., and at outlet of last reflux 83.2° C. Water required to keep catch tower outlet clean, 73 gallons per hr., or equal to 10.6% by vol. of liquor used. Lime used, 2½ cwt. per ton of 25% liquor. Crude liquor supplied, fixed NH_3 0.16%, free NH_3 1.55%; total, 1.71% = 7.88 oz. liquor. H_2S 0.20%. Desulphurised liquor, 1.39% NH_3 , 0.088% H_2S . Effluent, 0.010% NH_3 . Concentrated liquor made, 25.23% NH_3 and 0.42% H_2S by weight.

It will be seen from the above that the amount of water required to keep the catch-tower outlet clean was rather large, and not conducive to steam economy in the desulphuriser.

The various sources of ammonia loss were investigated and remedied as far as possible, but, unfortunately, it is not possible to give any figures relating to an improved efficiency of the plant because, before sufficient trials could be made, the plant, or rather portions of it, were changed over to the manufacture of sulphate of ammonia by order of the Ministry of Munitions, thus obviating, as will be seen, the chief sources of loss present when making concentrated liquor. The losses of ammonia in connection with a plant of the type in question may be due to the following causes:—(a) Desulphurisation. (b) Imperfect liming and boiling in the stills. (c) Pumping desulphurised, reflux pot and concentrated liquor. (d) Storage tanks. (e) Loading of rail tanks. (f) Leaks in the apparatus. These respective sources of loss will now be dealt with in order.

(a) There certainly remains much work to be done on the "decomposition" of ammoniacal liquor both from a general and an individual point of view and, as mentioned by Parrish,† the physico-chemical problems involved form "a subject which is peculiarly captivating to the student of applied chemistry and physics." In the present case lack of time has prevented any detailed enquiry so far. The steam pressure on the desulphuriser bottom tray averaged, over the period of working, 19 lb. per sq. inch; the average H_2S content of the liquor supplied being 0.21% and the total ammonia content 1.70%, while the desulphurised liquor averaged 0.061% H_2S and 1.48% total NH_3 . The finished liquor, as previously stated, contained 28.12% NH_3 and 0.45% H_2S . From these figures the hydrogen sulphide distribution works out as follows:—

	% H_2S .	% Removal.
Removed by desulphuriser	2.81	70.8
.. .. lime ..	0.71	17.8
Remaining in conc. liquor	0.45	11.3
	3.97	99.9

* Alkali, etc., Works Report, 1911.

† Gas J., 140, 557.

No systematic tests were made on removal of carbon dioxide. The average temperature at the top of the desulphuriser was 69.5° C., a supply of cold liquor being admitted to the top tray for purposes of control. The liquor from the catch tower was pumped into the third tray from the top and the hot main liquor supply into the fifth.

The catch tower has five trays 36 in. diameter and 8 in. deep. The total height including the bottom box is 5 feet. In this portion of the plant the most serious ammonia losses occurred. The condition aimed at was the minimum cold water supply requisite to retain all the ammonia, in order to avoid throwing extra work on the desulphuriser. Although a test cock was fixed in the last tray but one and instruction given to the attendants to test the gases there with litmus paper every half hour, ammonia escaped at times to the purifiers. At the time of testing, the tower might have three sections cold while a few minutes later, with the water supply unaltered, a change in the desulphuriser conditions would send forward a rush of gas and ammonia would be lost. In order to keep a check upon the working of the tower, a thermograph was connected with the last tray but one in order to record to within 0.5° C. the temperature of the liquor in that particular tray and so, indirectly, to indicate whether ammonia was passing. An improved efficiency is expected from the use of this instrument, but the plant was closed down before this was proved.

(b) With regard to the ammonia stills themselves, during the time the plant was in work it was impossible, owing to lack of boiler power, to work the plant to its full capacity. The lime mixer required cleaning out about once a fortnight. The effluent from the stills during the period of working averaged 0.011% NH_3 .

(c) The losses which occur due to pumping are difficult to determine and may attain considerable proportions. An Evans pump, 5 in. \times 4 in. \times 6 in., is fitted for pumping the desulphurised liquor and needed packing every two or three days at the liquor end. After trying various types of packing special S.E.A. rings were fitted and they had remained tight for three weeks, when, as previously mentioned, the plant was changed to the manufacture of sulphate of ammonia. The concentrated liquor pump, with ordinary care, and owing to not being used so frequently, gave little trouble. An Evans pump, 4 in. \times 3 in. \times 4 in., fitted for the purpose of dealing with the hot liquor from the reflux pot, gave much trouble. In order to avoid considerable leakage this pump had to be packed daily, due to the pump rod being rapidly attacked, apparently owing to the action of cyanides, and so developing a "shoulder." In the course of three months the rod was reduced in diameter by $\frac{1}{2}$ in. where in contact with the liquor. When the plant is restarted other types of rod will be experimented with.

(d) The storage tanks, two in number, are connected by 2-inch pipes with a small apparatus known as a "bubbler," the function of which is to deal with the ammonia gas expelled from the tanks. It resembles a small still and has four trays 21 inches in diameter; when fed with a dribble of water from a $\frac{1}{4}$ -inch pipe it is quite capable of dealing with the gases normally expelled, the weak liquor thus formed flowing to the reflux pot and thence to the lime mixer. Should the storage tanks become warm, however, ammonia escapes from the bubbler unless the stream of water is largely increased; an apparatus with a larger area would have been preferable. Careful attention should therefore be given to the outlet temperature of the final condenser. No trouble has been experienced by choking of the bubbler trays as, fortunately, the water supply is fairly soft.

(e) This source of loss is one which, at first sight,

seemed of small consequence, but upon investigation yielded surprising results. Rail tanks are usually provided with a loading or delivery pipe which reaches to within 2 or 3 inches of the bottom, while the displaced gases escape through a smaller hole in the top of the tank. It was at first thought that, by merely connecting this outlet with a 40-gallon cask of water, the ammonia escaping from the tank would be absorbed. However, after loading a tank an olfactory examination of the cask contents was unpleasant. Other casks were therefore prepared containing definite volumes of sulphuric acid and determinations carried out on the total ammonia displaced upon loading six 10-ton rail tanks. The figures obtained showed an average loss equal to 15 gallons of 25% liquor per tank. This figure must only be taken as approximate, because many factors, such as rate of pumping, strength of liquor, and atmospheric conditions influence the result. The tests were carried out during the month of February, the atmospheric temperature being about 50° F., while the liquor in storage was 65° F. In order to avoid the loss of ammonia while loading tanks, a pipe was permanently carried to the "bubbler," which was fed with extra water during loading, the rail tank being connected to the pipe by flexible hose.

(f) Frequent examination is necessary, because small leakages readily develop into large ones and often become all the more difficult to rectify. All gauge cocks should be moved daily because if once fixed they readily break, being made of cast iron. Careful warming up of the plant is one of the best methods for preventing numerous small leaks on the still and reflux condensers.

No attempt, as indicated by the title, has been made in this paper to exhaust the numerous problems arising in the manufacture of concentrated liquor, but merely to point out various sources of loss and suggest how they may be minimised. It must also be remembered that much remains yet to be accomplished in the design of plant, for although many plants will yield a product of specified quality they will only do so at the expense of disproportionate quantities of steam and cooling water.

In conclusion the author desires to express his thanks to Mr. J. Wesley Whimster, Engineer and Manager of the Bath Gas Light and Coke Company, for permission to publish particulars relating to the above plant.

DISCUSSION.

Mr. P. PARRISH remarked that the problem of the desulphurisation of ammoniacal liquor had hardly been approached scientifically. Most makers of plant had assumed that a long column still, designed on the lines of an ammonium sulphate still, would answer satisfactorily as a decomposer. No attempt had been made to dissect the respective operations involved in the desulphurisation of gas liquor. He had found that, within limits of 3 lb. pressure—i.e., about 6 in. mercury gauge—above atmospheric pressure, there was a practically coincident relationship between the boiling-point of water and the point of almost complete dissociation of the ammonium sulphide and ammonium hydrosulphide present in ammoniacal liquor. Further, to conform to the Ministry of Munitions specification in respect of concentrated ammonia liquor—viz., 25% NH_3 with a maximum of 0.5% H_2S —it was necessary that the gas liquor in the terminal tray of the decomposer should attain a temperature coincident with the temperature at absolute pressure, to which the liquor in the bottom, or terminal, tray was subjected. Having established this, it was readily conceivable that appreciable volumes of steam, ammonia, carbon dioxide, and hydrogen sulphide were released. It would appear that the most judicious arrangement

of plant was one which dissected the operation of desulphurisation into three parts—dissociation or decomposition; cooling; absorption. The dissociator should preferably comprise a still with about five trays, affording adequate area for the ascent of the gases, and equally adequate space for the descent of the liquor. To facilitate the recovery of the ammonia released in the dissociator, it was necessary to control the temperature of the gases leaving the latter apparatus. This could best be effected by cooling the liquor, by passing it through a multitubular cooler, so as to attain efficient absorption of the ammonia in the absorbing vessel. The absorber should be constituted of about eight trays in all, softened water being admitted to the top tray; the gas liquor to be desulphurised should be introduced to the fifth tray from the top. Plant designed on this basis, he believed, would be capable of fulfilling the assigned functions efficiently, and more economically in point of steam consumption than the majority of decomposers supplied hitherto. As regarded the losses of ammonia, he thought that the author had insufficiently emphasised the loss likely to arise from the effluent liquor from the ammonia still. He advocated the use of a pump provided with multiple glands for the concentrated ammonia liquor, so as to obviate loss of ammonia at this point.

Mr. MARSDEN, in reply, said he agreed that Mr. Parrish's method of desulphurisation was a good one; but as there were a large number of plants of the Wilton type—very similar to the one he had described—in use, he thought the difficulties he had described might help some of those who had to work these plants. At the same time, he agreed that Mr. Parrish's method would be preferable to the large type of desulphuriser fitted by the makers of the Wilton plant. The percentage of ammonia in the effluent during the test was taken by means of a Whitehead sampler, which took samples every hour.

NOTES ON THE CATALYTIC AND THERMAL SYNTHESSES OF AMMONIA.

BY E. B. MANTED, PH.D., B.Sc.

The direct combination of nitrogen and hydrogen with formation of appreciable percentages of ammonia may take place under two entirely distinct sets of conditions. Firstly, according to the well-known Haber synthesis, nitrogen and hydrogen are allowed to react, at a moderate temperature and at a high pressure, in the presence of a suitable catalyst such as iron. In the second place it has recently been shown by the author that the percentage of ammonia in equilibrium with nitrogen and hydrogen at a given pressure firstly sinks with increasing temperature in accordance with Haber's observations, then passes through a minimum value, and finally rises once more until at, for instance, the temperature of the high tension arc, the percentage of ammonia in equilibrium with its component gases at atmospheric pressure has risen to nearly 2% by volume, a value through which it has already passed on the other (i.e., the decreasing) side of the equilibrium temperature curve at a temperature of about 320° C.

It is proposed, in the first part of the present paper, to discuss quite briefly several points of interest which have arisen in the course of work on the Haber synthesis of ammonia, the second part of the paper being devoted to some description of the methods employed and results obtained in connection with the measurement of the ammonia equilibrium at high temperatures.

Part I.—Catalytic synthesis.

From the point of view of efficiency it would appear desirable to operate the synthesis under

such conditions that each litre of catalyst space gives the greatest possible yield of ammonia per hour, in other words so that the number of kilos. of ammonia per litre of catalyst space per hour, is at its maximum value. This is undoubtedly true in so far as it concerns the desirability of employing as active a catalyst as possible, provided of course that this catalyst has sufficient power of resistance to possible traces of "poisons" in the circulating gases; but it requires considerable qualification where a high yield of ammonia is obtained by means of rapid circulation.

If, in this connection, the progress of ammonia formation with increasing time of contact between the gas and the catalyst be noted and the yield of ammonia calculated for each case, it will be seen, as is well known, that the maximum yields of ammonia are obtained in conjunction with a short time of contact and consequently with a low percentage of ammonia per passage.

Table I., which records a typical result with an iron-potash catalyst at 550° C. and at 150 atmospheres pressure, is illustrative of this point.

The improved results over and above those reported last year are due principally to a modification in the method of working.

TABLE I.

Time of contact of gas with catalyst in seconds.	Percentage of ammonia formed.	Yield of ammonia in kilos. per hour per litre of catalyst space.
0.34	0.65	2.7
0.56	0.94	2.3
1.8	1.8	1.4
3.6	3.2	1.25
7.2	4.7	0.91
10.8	5.1	0.65
24.5	6.8	0.38

The highest possible yield of ammonia for a catalyst chamber of given size is thus obtained with a very high speed of circulation and with a minimum value for the percentage of ammonia formed per passage.

It must, however, be remembered that any decrease in the percentage of ammonia formed per passage involves a corresponding increase in the number of passages of the gas mixture through the catalyst chamber while each kilogram of ammonia is being formed, and that this necessitates an ever increasing amount of work in order to compensate for the deficiencies of the heat exchangers, also of those connected with the refrigeration system where this method of ammonia elimination is employed in preference to absorption by water.

It will accordingly be seen that the most economical conditions for the synthesis do not correspond with those necessary for a maximum yield per hour, but that an optimum rate of circulation exists, which can easily be calculated for a given system from measurements, with various rates of gas flow, of the temperature differences at like ends of the exchangers employed.

The next point which appears to call for attention is that of the most suitable working pressure. It is obvious that a low-pressure system presents many conveniences in working, principally in connection with the possibility of employing larger and simpler furnaces than are applicable for higher pressures. On the other hand any increase in the pressure employed leads to a corresponding increase not only in the value of the equilibrium ammonia percentage for a given temperature but also in the velocity of formation of ammonia. Further, since the power required for the initial compres-

sion varies directly as the logarithm of the pressure used, a high-pressure system will entail very little extra expenditure of power for compression over and above that required for a system working under a comparatively low pressure. Thus, if we take the power required to compress a gas mixture to fifty atmospheres as unity, that required to compress up to 100, 150, and 200 atmospheres, respectively, is 1.2, 1.3, and 1.35. Lastly, a high-pressure gas exchanges heat better than one at a low pressure and requires therefore less expenditure of energy in the exchangers, while, on account of the smaller size of the complete plant, radiation losses are comparatively small.

The relative values at various working pressures for the percentage of ammonia per passage and yield in kilos. per hour per litre of catalyst space with the same catalyst and under the same conditions as those employed for Table I. may be seen from Table II.

TABLE II.

Velocity of flow of gas in cubic metres per hour at N.T.P. per litre of catalyst space.	50 Atm.		150 Atm.		180 Atm.	
	% NH ₃ formed.	Yield in kilos. per litre per hour.	% NH ₃ .	Yield.	% NH ₃ .	Yield.
20	2.2	0.34	4.85	0.75	6.7	1.0
30	1.2	0.37	3.7	1.1	5.4	1.65
60	0.8	0.37	2.9	1.35	4.5	2.1
80	0.65	0.4	2.25	1.4	3.9	2.4
100	0.55	0.42	1.8	1.4	3.5	2.7

It will be noted that even at 50 atmospheres pressure it is possible to obtain a fairly high percentage of ammonia per passage, associated with a moderate amount of power for compression, by providing the plant with a series of relatively large catalyst chambers, which may be of simple design. There are, however, disadvantages of the nature already discussed and it would appear more economical in practice to employ as high a pressure as is compatible with ease of working, 180 atmospheres being found very suitable.

TABLE III.

Catalyst, iron-potash. Pressure=150 Atm.

Time of contact in seconds.	T = 530° C.		T = 580° C.	
	% NH ₃ .	Yield in kilos per litre per hr.	% NH ₃ .	Yield.
0.6	0.96	2.4	1.5	3.5
1.0	1.3	2.0	2.4	3.3
1.5	1.7	1.7	3.2	2.9
2.0	2.05	1.4	3.8	2.6

Thirdly, dealing with the question of a suitable working temperature, it must be borne in mind that, as the synthesis is usually carried out, the percentage of ammonia formed per passage never approaches the equilibrium value for the temperature and pressure used, and thus, within limits of course, reaction velocity will play an even more important rôle in the determination of the amount of ammonia formed during the time of contact than the absolute value of the equilibrium ammonia percentage. If, on the other hand, the temperature employed be so high that the desired percentage of ammonia unduly approaches the equilibrium percentage, the increase in reaction velocity due to increased temperature will no longer compensate for the decreased equilibrium ammonia content; further, at unduly high

temperatures the catalyst becomes less active owing to sintering.

The advantage of increasing the temperature, notwithstanding the decrease in the equilibrium ammonia percentage, is shown in Table III. for temperatures approximating to 530° and 580° C. respectively.

In concluding these notes on the Habber synthesis, I should like to thank Mr. G. F. Hanna for his assistance in the determination of the experimental data given above.

Part II.—Thermal synthesis.

While the possibility of a thermal synthesis of ammonia is certainly of considerable general interest at the present time, it would be just as certainly premature to discuss any possibility of its technical application, especially with the very limited amount of knowledge which is available. The nature of ammonia equilibria at high temperatures and the methods which have been employed for their determination appear, however, to deserve discussion, and it is felt that the following notes may well be given without apology as to their only indirect technical interest.

It appears desirable in the first place to give some description of the determination of the approximate value for the ammonia equilibrium at the temperature of the high tension arc. In order to obtain this value it is necessary to "freeze" equilibrium by an extremely rapid cooling of the gas mixture from arc temperature to below that at which ammonia decomposes with measurable velocity. This rapid cooling is effected only with considerable difficulty when a comparatively large arc is employed, but may be carried out extremely simply with an arc of small dimensions. For the measurement of equilibrium the arc is allowed to burn within a capillary tube in order that the whole of the gas, which during

terminals of an induction coil to approach until the spark discharge becomes transformed into a small and apparently continuous high tension arc flame of high temperature. Spark discharge as such has only a comparatively feeble effect on the combination, as was observed, for instance, by Deville and later by Donkin, and it is found that energetic formation of ammonia only takes place when the electrodes are brought so near together that a small more or less continuously burning high tension arc flame is formed instead of a spark.

Equilibrium at arc temperature was determined by observing the progress of the reaction, $3\text{H}_2 + \text{N}_2 \rightleftharpoons 2\text{NH}_3$, from both sides. The apparatus employed is illustrated diagrammatically in fig. 1. It consists of a graduated U-tube, A, provided with a three-way capillary tap at the top of its graduated limb and with a small outlet cock at its bottom near the bend.

This tube, which has a capacity of 100 c.c., is connected, as shown in the figure, to a capillary tube, B, which is bent twice at right angles, and passes by way of a second capillary three-way stopcock, C, to the small absorption vessel, D. D contains very dilute ammonia-free sulphuric acid and is provided with a wide side-neck and with a stopcock for filling and emptying respectively. At a convenient place in B two platinum wire electrodes, F and G, are inserted, leaving a spark gap of the required size, which for the measurements about to be described was 0.5 mm., the tube containing this spark gap being 0.6 mm. in internal diameter. E is a tap funnel containing mercury and provided with a removable jet, by adjusting the size of which the gas contained in A may be caused to flow at the required rate through the small arc and into the dilute acid contained in D.

The determination of the percentage of ammonia formed with a given time of contact with the small arc was carried out by filling A with a nitrogen-hydrogen mixture (25% nitrogen, 75% hydrogen) through its three-way cock, this being effected by allowing the mercury, with which A was originally filled, to flow out of the small tap provided for that purpose at its bottom. This gas was then driven at the required rate through the arc by allowing mercury to flow into A from the tap funnel, E, by way of a jet of suitable size. The tap, C, is, for determinations of ammonia formed, left in constant communication with D, and may if desired be omitted. At the end of the experiment the arc is stopped and the dilute acid in D, containing the ammonia produced, is run into a tall cylinder, and the ammonia estimated by means of Nessler's reagent. It was found inadvisable, on account of frequent fractures, to employ a heavy discharge for arc formation, the most satisfactory conditions being obtained with a "two inch" coil supplied with a primary current of about 3.5 amperes from the laboratory 220-volt main.

Fig. 2, bottom curve, shows the percentage of ammonia formed with various times of contact and it will be seen that a gas containing 1.5% of ammonia by volume is produced with a contact of 0.004 second. It is difficult to estimate the temperature of the small high tension arc formed, which, however, for the purpose of obtaining rough comparative figures for the various times of contact has been assumed to be about 3000° C. The rise in the ammonia yield with increasing temperature at high temperatures (in contradistinction to the fall with increasing temperature at moderate temperatures) is to be noted, and it will be seen further that sufficiently rapid cooling for the retention of the ammonia produced is effected

FIG. 1.

the course of the experiment is passing through the capillary, may be subjected as uniformly as possible to the heat of the arc flame. It has been found that a very convenient arc of small dimensions may be formed by causing the secondary

in this case by contact with the relatively cool walls of the capillary.

This synthesis curve would seem to indicate that the equilibrium ammonia content for a hydrogen-nitrogen mixture under the above conditions is between one and two parts per cent. by volume.

FIG. 2.

Accordingly it was considered interesting to study the effect of passing through the small arc a nitrogen-hydrogen mixture, as before, but containing 3% of ammonia. This ammonia content, being above the equilibrium value, sank instead of rising after contact with the arc, the experimental results obtained with various times of contact being shown in the top curve (decomposition curve) of fig. 2. In this case, the gas was, by operating C, only allowed to pass through D during the actual experiment. It will be seen that the equilibrium ammonia percentage appears to lie at about 1.7% for atmospheric pressure under the conditions studied. Finally, an attempt has been made in fig. 3 to

FIG. 3.

plot out the complete experimental ammonia curve up to about 3000° C. The figures both for temperature and for equilibrium ammonia content are very rough approximations only, except for temperatures below 1000° C. where ammonia formation

is effected catalytically according to Haber's measurements. The values for temperatures ranging from 1000° to 2300° Abs. have been determined by the sudden cooling of a nitrogen-hydrogen mixture in flames burning under water in a manner already described in detail (this J., 1918, 105 T).

While it is not proposed to discuss in the present paper the influence of pressure on the thermal synthesis, it is, however, interesting to note in connection with these earlier results that an increase in pressure from about one-tenth of an atmosphere to one atmosphere has given the anticipated increase in the amount of ammonia formed.

SCIENTIFIC GLASSWARE.

BY DR. MORRIS W. TRAVERS, F.R.S.

Before the war the whole of the light hollow glassware used in our chemical laboratories was imported into Great Britain from enemy countries, and practically the whole of the glass tubing and the glass instruments were obtained from the same sources. In August, 1914, supplies were cut off; and though the stocks held by some dealers in these goods were perhaps unusually large, it soon became clear that, should the war last for more than a few months, our industries, our public health organisations, and our hospitals would be seriously handicapped.

A few days after the outbreak of war I met my friend Mr. Douglas H. Baird, Chairman of Messrs. Baird & Tatlock (London), Ltd., who explained the position to me, laying particular stress upon the importance of chemical glassware in the steel industry, upon which a heavy strain was likely to be thrown, and upon the demand for glassware by the Army Medical Department and the hospitals. He told me that his firm were already considering the possibility of manufacturing scientific glassware upon a scale sufficient to carry them over the war, and were endeavouring to secure the co-operation of other dealers. He asked me if I would assist him, and I readily agreed, though I admitted that I had no wider experience of chemical technology than the average academic chemist. I may say that now, after spending almost the whole of my time during four years actually in the works, I approach the great problem of science and industry in a more humble spirit than may have possessed me when I was a professor of chemistry. I am inclined rather to blame academic chemists for the neglect of industry than the manufacturers for the neglect of science.

Mr. Baird's negotiations with other dealers came to nothing, and his attempts to interest certain glass manufacturers in scientific glassware were equally fruitless, so he decided to finance the undertaking himself. Professor H. B. Baker, F.R.S., had in the meantime very kindly placed at my disposal a laboratory in the Imperial College of Science and Technology, to enable me to complete a piece of scientific work which I had commenced in India, and in the month of October, 1914, in conjunction with Mr. Baird and Mr. T. Allen, a director of Baird & Tatlock (London), Ltd., I commenced an investigation on the glasses manufactured in Germany. Mr. Baird and Mr. Allen supplied me with a very large number of samples of glass, and with the fullest information as to their origin, qualities, and the opinions of their clients upon them. Thus, with regard to glasses for "lamp working," that is to say working with the table blow-pipe, I was able to obtain the opinions of skilled glassworkers, who used this material in very large quantity. "Jena" glass, "R" glass, Bohemian glasses, and glasses used for minor apparatus, such as test-tubes, and for heavy hollow ware, such as desiccators, were all reviewed and analysed, and at the end of four months I had obtained a fair insight

into the nature of the glasses used in making scientific glassware. A very considerable number of complete analyses were made at the time, and the analytical work carried out afterwards at the works upon thermometer glasses, lamp glasses, etc., extended our knowledge of the subject. I must remark here upon the very slight amount of information which was to be gained from scientific and technical literature upon the subject of glass.

It was decided to erect a glass factory in Walthamstow, adjacent to Messrs. Baird & Tatlock's scientific-instrument factory, and before commencing operations Mr. Baird secured the services of Mr. F. Winchurh, a highly qualified glassworker, as technical expert, and to his initiative, skill, and endurance such success as we have attained to is largely due. In the month of March, 1915, a small oil-fired furnace, capable of founding glass in quantities of about 1 cwt. at a time, was erected on the site of the works, in a temporary shed, and Mr. Winchurh and I proceeded to experiment on the basis of my analyses of glasses and raw materials. Batches were made up first from chemicals corresponding as nearly as possible to the constituents of the glasses, and then using commercial materials such as china clay, felspar, etc. Tube and hollow articles, such as beakers, were made from these glasses, and their properties were tested.

We now decided that we could make a soda-potash-lime-alumina glass, equal to the best German lamp-working glass, and a resistance glass similar to the "Jena" resistance glass, but modified in a manner calculated to remove the objection that the "Jena" glass gave up zinc to acids. My judgment upon this point has been confirmed by the results of a careful investigation recently carried out by Professor Turner and his staff in the Department of Glass Technology, Sheffield University, which has proved that "Duroglass" resistance glass is the most highly resistant to chemical reagents of any glass yet placed upon the British market.*

We next proceeded to build a larger oil-fired furnace for pots holding about 2 cwt. of glass. At that time Government was anxious for manufacturers to adopt oil fuel, but our experiments led to the conclusion that, though oil-firing was applicable to tank furnaces it was not suitable for pot furnaces, and the rapid increase in the price of oil during the second quarter of the year 1915 completely negated any advantage which might arise from the use of it. The experiments were therefore brought to a conclusion. By means of this furnace we were, however, able to manufacture glass in sufficient quantity to experiment further on the blowing of hollow ware, and it did good service in enabling us to manufacture some articles which were urgently required by Government in connection with gas warfare.

We had now to erect a furnace capable of producing glass at the rate of at least 5 tons per week, with the least possible delay, and we decided upon a type, actually in use, which was based upon the principle employed in connection with the gas-firing of horizontal gas retorts. It was a four-pot furnace, for 36-in. by 38-in. covered pots, each contained in a separate arch, and heated by gas from coke in a producer. The gas, issuing from nostrils, as in the gas-retort setting, met the secondary air, and burned below the siege, upon which the pot

in each arch rested, and the flames passed up channels at the side of the siege, surrounded the pot, and escaped through a flue at the top of the arch into the stack. The furnace was non-recuperative, and consequently not an economic one, but it cost little to build, and was erected and at work in six weeks. After I had entirely redesigned the setting, so as to burn the gas at the sides of the arch, and a little below the level of the top of the siege, instead of underneath the siege, it gave excellent results. It is still at work, and three, and sometimes even four, pots of tube metal, which is by no means too easy to plain, can be obtained from each pot every week. It does not give us much trouble now that we understand it. Later, we built a six-pot furnace of the same type, which has given good results, so far as output of glass is concerned, but which is very extravagant of fuel. We are now installing two Hermansen recuperative furnaces in a new glass-house.

In speaking of furnaces the efficiency is often expressed in terms of glass founded per ton of fuel consumed, but the expression is misleading, for the fuel consumption cannot be materially reduced while the pots are being worked, and the rate at which they are emptied depends upon the nature of the goods being blown. Two men will empty a half-ton pot of glass in a few hours making five-litre flasks, but six men might work for a couple of days out of a similar pot blowing small articles.

Unless the furnaces run well metal will run short, and what is much worse, the metal will be bad. But if the glass pots will not stand the heat, and continually crack, work may be brought to a standstill altogether. During the past year or two a great deal has been heard about the inferiority of English pots generally, and the cause of trouble with pots has been attributed to the fact that the demand has obliged manufacturers to use them before they are properly matured. However, having made a systematic study of the question, I have come to the conclusion that the fault lies mainly, though not entirely, with the glass makers rather than with the pot makers. The most usual complaint is that the pots split down the front, either through, or below the lip. The reason is as follows. The green pots are first heated in a separate furnace, the pot arch, usually direct fired with coke or coal to a temperature, which is not as a rule determined, but which probably rarely reaches 1100° C. The pot is then transferred to the glass furnace, and the front is built up, leaving the working opening, which is closed by a loose clay stopper. As soon as the pot has apparently attained the temperature of the furnace it is filled.

Now, the firing of a green pot in a furnace in which the pot is exposed directly to the flames is obviously a delicate process, and when one considers that the stoking is carried out by two or three shifts, it is somewhat remarkable that so large a proportion of the pots survives the process at all. Indeed, unless the pot is carefully made, and allowed to mature for a long time, it will not survive. If the firing were carried out in a muffle kiln, much trouble would probably be saved, and danger to the pots averted. Provided that sufficient care is taken, there is, however, no reason why the pot should be not quite sound when it is set in the furnace.

Now, when the temperature of the pot arch does not exceed 1100° C. the pot, when set in the furnace, is still in the biscuit condition, and if the temperature is then raised to 1300°–1400° C., as is usual in the case of any modern type of furnace, the material of it will become semi-vitreous in appearance, and the change will be accompanied by an increase of density from about 1.5 to 2.2, and by consequent shrinkage of the pot, the material of which will also become very much more

* Prof. Turner informs me that, as the result of a recent investigation, he has found that a 500-c.c. flask, after boiling for 130 hours with strong hydrochloric acid, during which time 9 litres of the acid was evaporated, dissolved to the extent of about 75 mgrms., or about 0.0001 gm. persq. dem. per hour. There was no selective solution of the constituents of the glass, which, so far as it dissolved at all, dissolved as a whole. Using the purest acid obtainable, the amount of each of the constituents of the glass which dissolved in the acid was, with the exception of the silica, less than the quantity of the same substance which was originally present in the acid.

highly resistant to the action of molten glass. However, if the ordinary procedure is adopted, while the back and sides of the pot become completely altered, the front remains in the biscuit condition, and owing to strains set up by the shrinking of the back and sides, cracks appear in the front, sometimes starting from the lip of the pot, sometimes appearing below it. When a small crack forms, owing to the low resistant qualities of the biscuit clay, it rapidly increases. Further, when the front of the pot is not properly burnt it rapidly corrodes, scaling from the inside, and being washed away on the outside by the glass which runs down between the pot and the pad below the lip.

When we set a pot in the furnace it is now our practice to build a temporary 9-inch wall, 9 in. from the front of the pot, so as to cover the opening of the furnace completely, and to leave the pot without touching it for three days. The temperature of the whole pot rapidly rises to the full heat of the furnace, and it becomes completely and uniformly burnt. The upper part of the wall is then pulled down and the front is built up for working. Special tools are used in this work, for the whole of the pot is white hot, but the operation presents no special difficulties. Though a pot is out of work for three days, the fact that its life is lengthened and that it does not scale, compensates for the loss of time.

During the war a good deal of work has been done in connection with the refractories used in the glass industry. This work has, however, generally been undertaken from the point of view of the laboratory, and not of the works. I cannot help thinking that the problems connected with glass pots should first have been attacked with a view to rectifying the faulty methods of burning the pots which are in common use, so as to enable glass makers to utilise to the best advantage the excellent material supplied to them by the British pot makers. No improvement in the material can compensate for unscientific works practice.

The making of glasses for use in the manufacture of scientific apparatus opens a very large field for research. Investigations on the composition of glasses which have been carried out by ourselves and others during the past few years have supplied us only with the bare minimum of necessary information. On the series silica-alumina-lime-soda-potash, with or without boric acid, there remains a vast amount of systematic work yet to be done by the chemist and manufacturer working in co-operation. We know, for instance, that a pure silica-alumina-lime-soda glass does not work as well before the blowpipe as a glass containing potash, and also tends to devitrify, particularly if it has been in stock for some time. But what is the proportion of potash to soda which will give the best result? Only a research conducted by the chemist, the glass manufacturer, and the practical glass-blower can tell us. Again, with certain proportions of potash the glass becomes difficult to free from minute seeds. Combinations of the same constituents for the manufacture of Petri dishes, and similar articles which must be highly resistant to the action of superheated steam, and as clear as "flint" when blown, also require investigation.

Glass is at the best a compromise, and this fact never becomes more evident than when one is considering the composition of the so-called resistance glasses. I should here like to call attention to the excellent work on the properties of these glasses which has been carried out by Professor Turner and his colleagues in the Department of Technology of the University of Sheffield, which will prove of great value to the manufacturer. However, while the manufacturer should do his utmost to provide the chemist with glassware which uniformly resists attack by ordinary chemical reagents, it must not be forgotten that the quality of the articles manufactured depends, not merely upon the chemical

composition of the glass, but upon properties which can at present only be determined in the glasshouse. If a glass melts easily it does not follow that it will plain easily, that it will be possible to work it over a sufficiently wide range of temperature to allow of economic production, or that it will not tend to become "cordy" upon the slightest provocation.

There is scope for a considerable amount of research on the mixing of "batch," and in connection with the mixing of batch and cullet. In the case of the batches used for making flint glass the roughest procedure may give excellent results; but while china clay may be used with invariable success as a source of alumina, when the batch is mixed mechanically, hand mixing of the batch containing china clay will produce, not glass, but a substance closely resembling pudding. I believe that considerable advantage is gained by grinding such materials as china clay with one other constituent of the batch. According to British glasshouse tradition, the cullet must be sieved to remove powdered glass, and therefore the grinding of cullet is a process which need not be considered. Actually, the cullet is sieved to remove accidental dirt, to which too little attention is paid in our glasshouses. Our observations lead us to the conclusion that considerable advantage may be gained from grinding the cullet, and mixing it with the batch.

The study of the formation of "cords" in glass is well worth attention. I believe that there are at least two classes of cords, but those which find their origin in ill-digested particles of clay, or scale from the pot, or from the material of the batch, may be ruled out of the investigation. A cord of this kind in a piece of tube, or hollow blown article, will be found to end in a little mass of jelly-like glass, sometimes surrounding an opaque particle. The glass-maker will say that these cords are due to "lack of heat," which is certainly true in the sense that if the pot is hot enough during the found, even fairly large particles of clay will completely dissolve. However, during the working of a pot of metal, the glass sometimes "goes cordy," and remains cordy, even when worked with a ring in the pot, and sometimes goes clear again in a truly remarkable manner. This is possibly a surface phenomenon, and is worthy of the attention of those who have made a study of colloids. I am collecting data on the subject, and shall be glad to hear of others who are interested in it.

Scientific glassware, made in the glasshouse, includes hand-made articles, articles blown in the mould and finished by hand, and articles which are blown in the mould and finished outside the glasshouse. Probably no foreign workman is the equal of the English craftsman at handwork, but though I hope we shall never see the famous English glasshouses abandoning art for industry, I do hope to see a less rigid adherence to old-fashioned methods of working, in connection with our new industry. The glass-worker's chair, as a machine, seems to me to be a very crude appliance for giving rotary motion to a blowing iron, and to the glass on the end of it, and should rank with the bow drill, and other implements of bygone ages. The glass-worker will tell you that he has more power over the glass while running the iron up and down the chair, but this appears to be one of those traditions which it is so difficult to overcome. In finishing such articles as beakers and flasks, and in many similar operations, which are carried out in the finishing shop, the chair has been abandoned for the machine, or mechanical arrangement, by which the article is rotated about its axis, without lateral movement, with the result that a comparatively unskilled girl can, after a few days' training, carry out operations which would otherwise have to be placed in the hands of a highly skilled workman. Further the girl's work on the machine is the more

satisfactory. Similar mechanical methods must be introduced into the glasshouse.

Except in the case of electric lamp bulbs, very little light hollow ware was manufactured in this country before the war, and, as may well be imagined, a good deal of experimental work had to be done before satisfactory methods were arrived at. Since I have become a glass manufacturer I have been amazed at the variety of common articles which the chemist and bacteriologist make use of. The result of this is that, while some few sizes of beakers and flasks can be made in fair quantity, the trade mainly consists in manufacturing comparatively small quantities of a large variety of articles. As neither dealers nor users hold large stocks, and are always asking for supplies in dozens of articles at short notice, the manufacturer is at a disadvantage. Were it possible to standardise chemical and bacteriological glassware, both the consumer and manufacturer would benefit. Owing to the variety of the goods to be manufactured, and the comparatively small demand for them, the introduction of automatic and semi-automatic machinery into this branch of the trade is at present hardly practical politics.

The question as to the thickness of the beakers and flasks has been the subject of careful consideration. Bohemian ware was always very thin, as the glass from which it was made was not resistant to heat. With resistance glasses it is possible to make beakers and flasks very much heavier than the Bohemian ware, and in this respect we, and the American manufacturers, have followed the practice of the makers of the Jena glassware. A 500-c.c. beaker should be about 0.8 mm. thick, and a 1000-c.c. beaker 1.0 to 1.2 mm. thick, but the articles must, of course, be evenly blown. Such articles as graduating flasks and X-ray bulbs must be blown exact to weight.*

The satisfactory annealing of the hollow-blown ware gave us more trouble than the whole of the other processes put together. When a beaker or similar article is blown, it is first annealed, then cut to the right height, flanged, badged, and finally re-annealed. The scientific part of the annealing process has been carefully studied by Mr. F. Twyman, of Messrs Adam Hilger, Ltd., who has also perfected an optical strain viewer, with which all our goods are tested before issue. However, the practical treatment of the subject was not easy, particularly as we were hampered by tradition.

The lehr which is used in most English glasshouses is an arched chamber upwards of 40 feet long, with a fire-box on one side, at the hot end. The articles when placed in the pan are heated directly by fire, and as the pans are drawn down the lehr they gradually cool off. This method serves to anneal even complicated hand-worked ware made from flint (lead) glass, but it proved totally inadequate for resistance beakers and flasks. This is somewhat surprising, for since the goods are light they should anneal easily. However, I believe that we have here to consider the existence of a skin effect, which may possibly be connected with the formation of cords to which I have already referred. This effect is not taken into consideration in dealing with the general problem of annealing, but its existence may account for the fact that unless the glass is thoroughly soaked at the annealing temperature it is not properly annealed. In the case of scientific glassware we are dealing with an enormous bulk for very small weight, and as the goods must pass very slowly through the hot part of the lehr, unusually large lehr accommodation is required. This is a fact which we altogether failed to recognise when we designed our first glasshouse.

The cost of town gas being prohibitive, we heat our lehrs by means of producer gas. The gas enters a space below the bed of the lehr, which is formed of a brick arch, and then passes up ports at the side. Secondary air enters through slides at the front, and meets the gas at the bottom of the ports, and the length of the flame issuing from the ports, and consequently the temperature of the lehr, can be increased or reduced by closing or opening the air slides. The temperature of the hot part of the lehr can be regulated by this means to within 10°, and as the hot gas from the producer heats the bed of the lehr from below, a uniform temperature can be maintained. The fall of temperature along the lehr is regulated by taking away the hot gases into a flue, through openings which are closed by dampers. Resistance glass may be removed from the lehr at 300° C.

It is neither necessary, nor possible, to anneal chemical hollow ware as perfectly as glass which is required for optical purposes. However, uniformity in the output is absolutely essential if the manufacturer is to inspire confidence in his customers, and therefore the problems connected with annealing demand his closest attention.

When a beaker, or similar piece of apparatus is blown, it resembles a bottle, and the next stage in the process is to cut it to the proper height. The process by which this is done is well known. The article is slightly scratched with a diamond, and placed on a revolving table, while a fine blowpipe jet plays upon it at the height of the scratch. If the goods are well annealed, and evenly blown, they crack off quickly and evenly, provided that the jet is properly adjusted. Badly annealed goods and badly blown goods crack off so as to leave jagged edges. Thus the efficiency of production depends very largely upon efficient first annealing.

The flanging and lipping of beakers, and the flanging of flasks, are operations which are carried out entirely by machines operated by girls. The designing of these machines did not call for a vast amount of ingenuity, but in perfecting the details it was necessary to study the processes very closely in the works. There is scope for the engineer in the finishing shop as well as in the glasshouse.

Space will not admit of a lengthy discussion of the problems of the graduating shop, but I should like to call attention to the very great scope for research in this direction, and to the curious fact that scientific literature includes very few papers dealing with the accuracy of volumetric measurements. Unfortunately, in this, as in other branches of the trade, a policy of secrecy acts as a bar to progress, and in establishing our department, which was undertaken in order to meet a national demand, Mr. F. C. Harris and I had to start at the beginning, and work out the various processes. Sir Richard Glazebrook, F.R.S., and Mr. Stott, of the National Physical Laboratory, kindly placed at our disposal data for the compilation of correction tables for determining volumes by weighing water, but this is the only information which we have been able to obtain from the outside.

Provided that the operator is supplied with tables from which the corrections for barometric pressure, and for air and water temperatures, can be read off easily, that due care is taken with the weighings, and that proper machines are used in reading and marking the level of the meniscus, there is no difficulty in manufacturing accurately marked flasks, and similar pieces of apparatus. However, the graduating of cylindrical vessels, such as measuring cylinders and burettes, presents greater difficulties. In the first place glass tubes, even when most carefully drawn, are never truly cylindrical, and the same remark applies to measuring cylinders, when blown in the mould. Before graduating, a 50-c.c. burette is usually marked at six points, so as to divide it into five lengths, each

* My attention has recently been called to the shrinkage of moulds used in blowing graduated flasks. That cast metal articles, when repeatedly subjected to heat and cold, do shrink is well known.

corresponding to a capacity of 10 c.c. Each length is then divided into 100 parts, but as the distance between the fixed points is more or less unequal, the lengths corresponding to 0.1 c.c. must change suddenly in passing each of the fixed points. The graduation is, therefore, at the best an approximation. A machine has been designed which, it is hoped, will make it possible to smooth out the irregularities automatically, by means of a mechanism retarding or accelerating the motion of the carriage of the dividing machine, and actuated by a cam working against a flexible steel bar, the curve in which corresponds to the correction curve for the tube. When once the curvature of the steel bar has been adjusted to correct the setting of the machine at the fixed points, the graduation of the whole length will be possible without further adjustment. The plans are in the hands of Messrs. Munro, of Tottenham, who have also made for us a machine for graduating measuring cylinders and similar instruments, based on the principle of similar triangles. One of these machines has been in use in our works for some time, and others are being made for ourselves, and for other members of the trade.

A good deal of work might well be done with a view to improving the ordinary dividing machine, in which the carriage is moved by means of a screw, driven by a ratchet wheel and a pawl attached to the divided head. The setting error may, of course, amount to $1 \div$ (twice the number of teeth on the ratchet wheel), and as the number of teeth is usually only 200, the error may be 1 in 400, which is too great for accurately graduated glassware. The accuracy with which the machine can be set must be increased, and means must be found to eliminate the "overthrow" of the screw, which introduces irregularities, unless the operator is very careful. Even mechanically driven machines are liable to this error, unless in perfect adjustment.

I may mention here a very useful, and simple method which we employ in determining volumes. A rod of pure nickel is bored and the hole is rounded at the bottom. The end of the rod is then carefully ground till the capacity, which is determined by filling the vessel, so formed, with mercury, and pressing a polished glass plate into the top, is exactly the volume required. In calibrating an instrument, like a burette, the glass tube is filled with water and the height of the meniscus is marked. Ten c.c., or any other volume, of mercury, is then poured into the burette from the nickel measure and, the sides of the tube being wet, the water meniscus will rise by an amount equal to the amount which it would fall if the same quantity of water were allowed to flow from the apparatus. The method, which is only a modification of one which is well known, has been proved to be one of very high accuracy, and might well be applied in the laboratory for the checking of glass instruments.

Anyone possessing mechanical ingenuity will find in the lamp-working shop a field for investigation. Manufacturers of electric lamps have for long been accustomed to employ machines for flanging glass tubes, and for sealing together the parts of the lamps, and the principles upon which their methods are based are capable of wide extension. However, while in the electric lamp factory the machines are generally designed to perform only specified functions, machines of a more "universal" type are required for use in the general lamp-working shop.

There is perhaps less difficulty in designing machines than in getting them made under war conditions.

Grinding, polishing, stoppering, and similar operations, which, in this country, are usually per-

formed by highly skilled workmen using very crude tools, demand the attention of the engineer.

In reviewing the work which has been done, and the results which have been attained, it must be admitted that we, and the other firms which are working on similar lines, are yet far from being able to supply all the varieties of scientific glassware previously imported into the country. As to whether the industry will survive the war is a question which I do not propose to discuss. It has, however, been scheduled by Government as a "key industry," and in establishing the Department of Optical Munitions and Glassware, Ministry of Munitions, we believe that the Government has in view, not only the development of the industry for war purposes, but its permanent establishment in the country. We hope that this department, which has succeeded in gaining the confidence of those engaged in the industry, will be able to play an important part in the work of reconstruction.

DISCUSSION.

Dr. CHARLES A. KEANE said that one of the principal difficulties in founding the scientific glassware industry was the financial question. The manufacture of test-tubes, for instance, had been a home industry in certain parts of Austria and Germany, carried out in small communities where families obtained their glass from the glass makers, blew the test-tubes at home and brought them back at a price many times less than we could produce them at present. Although they could not hope to establish these home industries here, yet they would like to be able to look forward to a cheapened method for making such essential commodities as test-tubes, at moderate prices. He asked what material was used for the moulds in which beakers, etc., were blown. With regard to the suggestion that the number of the sizes of flasks and beakers made should be reduced, he said that although it was very convenient to have a large range of these, it was open to discussion whether it was really necessary, and if they could help the glass industry and cheapen the products by accepting, at any rate as a temporary expedient, a few standard sizes, their work would not be seriously crippled.

Dr. F. W. RIXON asked if Dr. Travers had attempted to reproduce the effect obtained by superimposed layers of different types of glass one upon the other, also whether he considered he had obtained a soft glass tubing which was as workable before the blow-pipe as the ordinary glass obtainable in pre-war days.

Mr. W. J. A. BUTTERFIELD referred to the committee formed some years ago by the Society to deal with questions of standardisation of plant and apparatus and arbitrary methods of analysis, and expressed the hope that the question of standardisation of glassware would be referred to some committee of the Society in co-operation with the glass manufacturers. In regard to the question of thickness of glass, he said that for two or three years before the war he had been in the habit of using glass made at Ehrenfeldt, which was very much thicker than the Jena glass; it was equally good for high temperature work but was very much stronger. There was very often a thin patch in Jena glass which was apt to fall out when the vessels were used for violently bumping liquids or liquids which distilled with explosive violence; that did not happen with the Ehrenfeldt glass, but he believed the competition of the firm in question had become so severe that the Jena firm had bought it up.

Dr. BRISCOE supported strongly the suggestion that great simplification of laboratory stocks could be obtained by standardising and reducing

the number of sizes of glass apparatus. A range of some four sizes of beakers, say 250, 400, 700, and 1000 c.c., would probably cover all practical requirements, and he thought that the glass maker might take the matter into his own hands. It might also be possible to eliminate the smaller sizes of round-bottomed flasks; for all practical purposes the smaller sized flat-bottomed flasks were very much to be preferred. With regard to soft glass tubing for working with the blowpipe, he said that he had had considerable difficulty in obtaining glass which was really suitable for this purpose, most of the available supplies having a great tendency to devitrify.

The PRESIDENT referred to the great benefit that had been derived from the work of the Engineering Standards Committee in simplifying specifications for rails, girders, etc. The question of chemical standards was a matter in which their Society should take the lead, and he sincerely hoped the matter would not be lost sight of. In listening to the paper he had been struck by the fact that an industry working in such an exceedingly crude fashion should have survived. It seemed difficult to imagine that so much should be done by hand. Why should a boy be employed to blow into the end of a tube? Surely it was possible to produce a blast by mechanical means that was at least as reliable and probably cheaper. Obviously the only way of competing with domestic industries such as Dr. Keane had mentioned was to dispense with labour as much as possible and work in factories on a big scale with mechanical appliances, and he had not the least doubt that the solution of the commercial problem, at any rate, lay in that direction.

DR. TRAVERS, in reply, said that in this country we certainly could never introduce cottage industries such as obtained in Germany and Austria, and he should very much regret to see it done. The Japanese were making test tubes extremely cheaply, and that manufacture was being developed as a cottage industry. He believed that success or failure in this industry depended upon organisation. They had had to discover the methods adopted in Germany in making this glass, and in 99 cases out of 100 it had not proved difficult. The moulds at present were being made of brass for the reason that although the material was dear, it was much cheaper to finish a mould which was cast in brass than one cast in iron, the saving in labour amounting to about 75%. Their work was blown dry, although this was not the English practice as a rule. They did not use wet methods because there was less skin effect owing to less chilling, and therefore less annealing was required. The question of the thickness of glass was entirely one of care in annealing. In reply to Dr. Rixon, he said that he had heard recently that superimposed glasses were not a success because the thicknesses of the superimposed layers had to be kept within certain narrow limits; outside those limits an explosive mixture was obtained. He was glad that the idea of standardisation had been received sympathetically; if some of the sizes now made were ignored it would be possible to work with automatic and semi-automatic machinery and reduce the price very considerably. In reply to the President, apart from automatic and semi-automatic machinery in which blowing was done entirely mechanically, pressure blowing had been used for many years in the glass industry particularly for blowing very large articles like carboys and big globes from which watchglasses were cut. In the tube shop the boy was only blowing for a few minutes; when not blowing he was engaged in picking up glass and dropping it on the ladder to prevent it chilling, so that mechanical aid

would not pay in that case. Tube-drawing machines were in use in America for drawing tubes of comparatively small size, but there were none, so far as he knew, in this country. He believed it would be difficult to develop machines for drawing tubes more than $\frac{1}{2}$ in. diameter. In regard to soft glass tubes, he said that they had copied the German potash-soda tube, and the British product was now as good as the German. It must be a soda-potash glass containing 13% of soda and 7% of potash.

THE SEPARATION AND USES OF CACAO SHELL.

BY A. W. KNAPP, B.Sc., F.I.C.

The regulations recently issued by the Food Controller concerning cacao shell in cocoa have brought this subject again into prominence. Since the famous legal case in 1910 when a cocoa powder containing 18% of shell was found to be genuine, it has received little attention, and now for the first time in England the amount of shell that may be present in cocoa has been carefully defined.

The quantity of shell produced every year is sufficiently great to make the subject of interest to those who have to consider the scientific use of waste products. By calculation from the official returns on cacao, the world-production of cacao shell is found to be about 36,000 tons per year, of which Europe consumes 22,000 tons. The consumption in Great Britain in 1916 was 4773 tons.

The raw cacao beans of commerce are about the size of almonds and have a thin skin or shell. This averages about 12.5% by weight; the percentage varies with the size and method of production of the beans. Thus, when the shell has been washed, as in the case of the cacao from Ceylon, it amounts to about 8%, whereas with Trinidad cacao, which is clayed, it varies around 15%.

In the cleaning of the beans a small amount (about 0.2%) of loose shell fragments is separated. The shell cannot be easily separated from the bean in the raw state, but after roasting, the shell no longer adheres to the bean. It has apparently always been the custom to remove the shell, and to use only the kernels for the preparation of cocoa or chocolate; thus Willoughby in his "Travels in Spain" (1664) writes "They first toast the berries to get off the husk," and R. Brookes in his "Natural History of Chocolate" (1730) says:—"The Indians . . . roast the kernels in earthen pots, then free them from their skins, and afterwards crush and grind them between two stones."

After roasting, both the shell and bean are crisp and brittle, and the small hard radicle, or germ, is loose. All that is necessary to get them in a suitable condition for separation is to crush the bean with as little breaking down to powder as possible, so that the shell is in large flat plates and the bean in large solid fragments (nibs). This is frequently accomplished by passing through rolls at such a distance apart that the bean is cracked without being crushed. It may also be effected by using a serrated cone revolving in a serrated conical case. It is usual to pass the broken bean into a germ separator; in these machines use is made of the uniform size and rod-like shape of the germ to effect separation. The germs so obtained naturally contain some nib and fine shell, and this mixture is known as "smalls." The large nib passes on to the husking machine, in which the nib and shell are separated by winnowing in a powerful current of air, the large nib falling through the current, whilst the shell is blown into another compartment. Both nib and shell pass down revolving cylindrical screens, encountering a larger and larger mesh as they proceed and thus

being separated into various sizes. The current of air carries about 0.2% of the material as dust into a settling chamber. The large shell contains a fair amount of nib and is graded and separated. Starting with 100 parts of raw cacao beans 10½% of shell is produced. The total "smalls" obtained approach 4%, these "smalls" containing about 36% of shell. As a result of these separations and the loss which occurs on roasting, only 78.5% of usable nib is obtained, and this contains about 2% of shell. Continuous vigilance is required to keep the product up to this standard. The husking machine and shell purifiers occupy a considerable space. Crushing and separating machines to deal with 1 ton an hour occupy 2200 cubic feet, or roughly to handle 1 lb. of roasted beans per hour requires 1 cubic foot. The space occupied by the "smalls" machine, shell graders, and purifiers would add 50%. We have never heard of any other method of separation of the shell being used.

The price of cacao shell has undergone an extraordinary increase in the last two years. Thus in 1912 the average price was 65s. per ton; in 1913, 1914, and 1915, 70s.; in 1916 it rose to 90s.; in 1917 to 128s.; whilst in May, 1918, it stood at 310s. per ton. The variation in price is even greater than appears from these figures. To appreciate fully the rise we have to deduct the bagging expenses, which are high, shell being a bulky material. Thus the above shell, which is practically free from cocoa, weighs only 9½ lb. per cubic foot (or 32 lb. when ground to powder).

There are other grades of cacao shell from which the manufacturer has not so completely separated the cocoa, and these are more highly priced, *e.g.*,

Grade.	Cacao nib present.	Price per ton (Sept., 1916).
1.	less than 1 %	120s.
2.	2.8 %	130s.
3.	10.0 %	150s.
4.	15.0 %	200s.

The following are the most representative analyses:—

Analyses of Cacao Shell.

Shell.	Unroasted. Average.	Roasted. Average.	Roasted. Average.	
Water ..	12.51	4.50	4.87	% 9.30
Fat ..	4.23	4.40	2.77	3.83
Ash ..	10.20	7.30	10.48	8.26
Nitrogen	2.19	2.50	2.34	3.00
Fibre ..	16.71	14.00	15.63	13.85
Analyst ..	Zipperer	Booth, Cribb, and Richards	Winton, Silverman, and Bailey	Smetham

Cacao shells have long been sold in small quantities in Ireland under the name of "miserables" for the preparation of a table decoction. But it was not till this year that they were sold under fancy names at fancy prices, as much as 2s. per lb. being paid in some cases. Whilst a water extract has, no doubt, a small food value, cacao shell should be regarded as a substance capable of producing an

inferior stimulating drink rather than as one giving a food beverage. In this connection reference should be made to a recent paper by J. L. Baker and H. F. E. Hutton on "The Analysis of 'Cocoa Teas'" (Analyst, 1918, 43, 189). Cacao shell contains on an average 1% of theobromine (the figure given in most published analyses being too low), and this is probably its most valuable constituent when used to prepare a drink. Its proper use is as cattle food; for this purpose until the last six months it was low in price.

Smetham (J. Lancashire Agric. Soc., 1914) calculated the "food units" as 102, which places cacao shell above maize and meadow hay.

Mr. W. L. Dubois has sent us the following figures, obtained in America, showing the digestible nutrients in 100 lb. of shells:—Protein 1.53 lb., fibre 6.45 lb., nitrogen-free extract 40.6 lb., fat 4.91 lb., fuel value 111,079 calories (1 lb. gives 1191 B.Th.U.). These analytical results have been supported by practical feeding experiments in America, in Germany (see Zipperer), and in Turin by F. Faelli, who obtained an increase in the daily average yield of milk. J. E. Lucas (Bull. Agric. Intell., 1913) obtained 20% decrease in amount of milk and 20% increase of fat content. In 1916 it was reported that horses in Germany were poisoned by being fed on cacao shells (2½ lb. per meal). It was suggested that this was due to the theobromine present in the shell. We feel that this is doubtful, considering that cacao shells have so long been used in compound feeding cakes without complaint. It suggests however, that it is probably unwise to use a high percentage of it in a diet.*

Early in 1915 the transport difficulties were so great that manufacturers of cocoa could not get rid of their shell and hence some thought was given to ways of using it. It has been used as fuel. Its calorific value is a little greater than that of wood (varying from 7400 to 8600 B.Th.U.), but being very light it needs careful management. It is most effectively used on a gas plant, the only objection being that the tar which it produces has a nauseating odour. The charred residue can be used as a manure. The shell itself has been used as a manure (see Annual Report of the Experimental Farms in Canada, 1898, 151, and 1899, 851). In experiments at Bourneville it was found to decompose in the ground very slowly, and Mr. J. Lodge recommends that the decomposition should be hastened by placing the shell in a heap, soaking well with water, and turning several times previous to use on the land. Used in this way it gave excellent results both as a manure and as a lightener of heavy soils.

The fat in cacao shell can be extracted by solvents, and as "shell fat" is seen on the market from time to time; this is presumably a regular practice on the Continent. This solvent-extracted fat has an unpleasant taste and an odour like tobacco, which renders it unfit for edible purposes. With theobromine fetching fifty shillings a pound the extraction of the theobromine from shell appears a feasible proposition. We know of no firm actually doing this, although presumably either shell or germ is the source of the theobromine now sold. As an experiment we ourselves extracted some sixty pounds, which we had no difficulty in selling.

Shell can be made to give an extract which is equal to some of the coffee substitutes at present sold, and many other applications have been

* See "Cacao Shells as Fodder," by A. W. Knapp, Tropical Life, 1916, 134.

suggested, but the use of shell which is the most interesting and regrettable is in cocoa and chocolate. In Belgium, Switzerland, Austria, Germany, and America, it is illegal to put shell in cocoa or chocolate, the shelled bean being used. In Great Britain until this year the amount of shell that might be present in cocoa and chocolate had not been defined. The Food Controller has now issued regulations which state that "no person shall manufacture cocoa powder except such powder as contains no more than 5% of shell." A manufacturer "may sell as Grade A. cocoa powder any cocoa powder which contains not more than 2% of cocoa bean shell." From the point of view of the public and the manufacturer the figures are well chosen, for when every reasonable effort is made on a commercial scale to separate the shell from the nib, about 2% of shell is left in. These figures have, however, placed the analyst in a difficult position, for there is no process which will accurately determine such small quantities of shell as 2% and 5%, and with such processes as are available he will need to draw conclusions from his results with considerable caution. Of the many processes that have been suggested we have most confidence in the fibre determination, but the natural variations in shell and in nib are so great as to make the detection of 5% of shell uncertain (see also Baker and Hulton, Analyst, 1918, 43, 197—201).

In conclusion I wish to thank Mr. N. P. Booth for a number of useful suggestions.

DISCUSSION.

Mr. D. LLOYD HOWARD asked whether the feeding of cacao bean shell to cattle affected the flavour of the milk in any way.

Mr. C. J. WATERFALL asked whether the author had tried any other mechanical process for separating the shell than that which he had described. He had tested a great many samples of nibs for cattle feeding purposes with very good results, and had never heard any suggestion of taint being produced in the milk. What method was used to estimate the theobromine?

Mr. MILNES asked whether there was any great difference in the specific gravities of the shell and the nib.

Dr. H. W. BYWATERS enquired whether the author had obtained more theobromine from the roasted shell than from the unroasted shell. One would imagine that during the roasting a good deal of the theobromine would be eliminated; if that were so it was surprising to find that so much remained in the roasted shell. He suggested that another possible use for the shell was in the manufacture of paper. At the present time it would seem to be more profitable to use cacao shell as a foodstuff than as a manure.

Mr. KNAPP, in reply, said that he knew nothing as to the effect on milk supply through the consumption of cacao shell by cattle. His own view was that it should be used as an appetiser rather than as the main portion of the diet. For the estimation of shell he had tried the levigation process of Macara, which depended on the fineness of grinding of the shell; any difference in the specific gravity in water could easily be overcome by finer grinding. He had found very slightly more theobromine in the roasted shell than in the unroasted. Theobromine was very difficult to sublime; it required a much higher temperature than was necessary when roasting cocoa. He had tried various processes for estimating theobromine and thought that the Dekker process was undoubtedly the best.

OCCURRENCE OF MOULD IN COCOA BUTTER.

BY LILY BATTEN AND HUBERT W. BYWATERS.

Cocoa butter is distinguished among fats by its resistance to influences tending to produce rancidity or mouldiness. A case of extensive growth of a mould in a specimen of cocoa butter is therefore interesting and noteworthy. The specimen in question was a large block of butter weighing about 28 lb., and it had probably been expressed from the cocoa beans several months before it came under our observation. On being broken, it was noted that towards the centre of the block, and extending from the upper to the lower surfaces, were a large number of dull black patches, intermingled with streaks of a brownish yellow tinge; the butter had a granular appearance, the whole somewhat resembling a matured Stilton cheese.

An accidental contamination with dirt was at first suspected, but on microscopical examination the dark material was found to consist of innumerable hyphae of various kinds, and greenish blue conidia of a fungus. It was difficult to identify the individual genera in this mass, so sterile prune-juice agar medium was prepared, poured into Petri dishes, and subsequently inoculated from various parts of the infected material. In this way colonies of the moulds were obtained and *Penicillium glaucum* and pink yeast were found to occur, but the greater part of the original mass was found to consist of a species of *Aspergillus*. A pure culture of the latter was obtained, and it is believed to be *Aspergillus oryzae*. According to Lafar (Tech. Mycol., 1910, Vol. II., Pt. II., p. 308) this species is of practical importance as a saccharifying fungus, and has been cultivated for centuries in Japan for the production of saké from rice. It grows rapidly on a large variety of liquid and solid media, and is easily cultivated even at room temperature, the optimum being above 30° C. The peculiarities of the conidiophores, sterigmata, and conidia enable the species to be distinguished with comparative ease from most others, but it is similar to *Aspergillus flavus*, except that in the latter the walls of the hyphae and conidiophores bear irregular outgrowths. The clavate or spherical globule exhibits no definite line of demarcation from the smooth stem. The sterigmata are radial, and bear numerous large spherical conidia measuring about 0.006 mm. in diameter.

On breaking open the block of infected butter, drops of clear liquid, apparently water, were observed to be present in some of the larger vesicles. Chemical examination showed the infected part to contain 0.13% of moisture, and it was thought possible that the spores of the fungi had found their way into the butter by this means. To settle this question, the following investigation of the conditions of growth of *Aspergillus* was carried out:—Cocoa butter in sterilised Petri dishes was inoculated from the infected butter, and it was found that the mould would not grow on ordinary cocoa butter at any temperature from room temperature up to 33° C., which is its melting point.

Evidence of the facilitating influence of water on the growth of the mould in the infected block was then sought by preparing a series of sterile Petri dishes, and into them placing (a) ordinary cocoa butter, (b) sterilised cocoa butter, and (c) solidified emulsion of cocoa butter and water (containing about 30% of water). These were then inoculated with the spores of the fungus. In addition, small blocks of the infected butter were placed in contact with blocks of (a) ordinary cocoa butter and (b) solidified emulsion of cocoa butter and water. The dishes were then kept at various temperatures from 15° C. up to 33° C., but at the end of three months in no case could fresh growth of the fungus be observed.

However, colonies of fungoid growth had actually developed on a large block of the solidified emulsion of cocoa butter and water which had been kept at room temperature for the same time, and on reconsideration it appeared probable that the comparatively thin films of cocoa butter and water emulsion in the Petri dishes would rapidly become dry during the incubation, and any initial growth of the fungus would soon cease owing to the lack of moisture. This view was corroborated by the fact that in a dish where the block of medium was about as thick as the depth of the dish would allow, growth of the fungus was eventually observed at a temperature of about 27° C. The water content of this butter was 2.4% which is therefore sufficient to enable the mould to grow.

In all cases growth of the mould appeared to become quiescent after a comparatively short time, although subsequent re-inoculation into a fresh plate was again followed by spasmodic growth. In order to ascertain if the arrest of growth is due to lack of water or another substance, a series of blocks of cocoa butter containing from 0–20% of water in an emulsified state were prepared, and the fungus introduced into the centre of the block, instead of being inoculated into the surface layers. Under these circumstances, however, growth continued to be slow, no matter how large the proportion of water present, but it was rather quicker at 27° C. than at either 12° C. or 17° C.

These experiments seem to indicate that although water is necessary for the growth of the mould, yet the cessation of growth is due to a lack of some other food substance. Although nitrogen could not be detected in the original block by the usual tests, it was thought possible that the addition of a nitrogenous substance might render the cocoa butter more suitable for the propagation of the fungus. Sterile Petri dishes were therefore prepared containing a medium of cocoa butter mixed with a small quantity of sterile prune-juice agar. These were inoculated, and, on incubation at 27° C., vigorous fungal growth was observed in less than a week. Fructifications were also formed in the following days, with development of characteristic conidia.

These results show that no fear need be entertained of ordinary cocoa butter becoming mouldy from the cause under investigation, provided it is kept free from water. If, however, water finds its way into the cocoa butter—and especially if the water contains substances, probably of a nitrogenous nature, which can serve as food for the fungus—then there is a real danger of the cocoa butter becoming mouldy.

Chemical investigation showed that the acid value of the mouldy butter was about 13, but this was largely due to the presence of the fungoid material, for the acid value of the butter after filtering through paper was only 3.8. This figure, although comparatively low, nevertheless indicates a certain amount of free fatty acid in the butter, and suggests the probability of the appearance of rancidity if the growth of the fungus is unchecked.

The greater part of the experimental portion of this investigation was carried out in the Department of Botany of the University of Bristol.

DISCUSSION.

Dr. S. JUDG LEWIS said that it might happen even with perfect storage that the brown paper in which the 28-lb. blocks were wrapped, or the sack containing a number of such blocks, might have a growth upon them. In the one or two instances in which he had seen mould growth, water had always been present. The figure given by the authors of 2.4% of moisture in cocoa butter emphasised the importance of keeping out water in the manufacture, particularly as cocoa butter was liable to contain cocoa material, which would be

sufficient to supply the nitrogen which the authors had found necessary for the development of the mould.

Mr. J. ALLAN said that there was one point in connection with the storage of fats which accentuated the difficulties arising from the presence in them even of very small quantities of water. It was well known that the fats which were solid at ordinary temperatures had a great tendency during solidification, particularly if it were prolonged, to develop a condition which was known as "seed," i.e., the mass became more or less granulated. Usually in solidification of fat under these conditions, the portion which solidified first possessed little or no structure; the granular structure, which was generally in the centre, was almost akin to crystallisation. At the same time the water in the fat tended to pass towards the centre of the mass, resulting in a higher percentage of water in that part. Consequently the mere estimation of the original water content of the fat was not a safeguard against such conditions as had been put forward in the paper. If it was intended to store fats of this kind for any length of time, care should be taken to avoid this granulated structure. It was not infrequent to find it in parcels of high-grade tallow arriving from Australia or America, even though care had been taken during cooling and packing to get them as nearly as possible homogeneous in texture, and red, green and black moulds were often found in the centre of the packages.

Mr. A. W. KNAPP asked in what manner the water was extracted from the mass. Was the water distributed in the form of an emulsion or was it distributed in fissures in the mass? He also asked what was the ash content of the fat, i.e., if any alkali had been used in its preparation.

Dr. BYWATERS, in reply, said that the particular sample of cocoa butter had been filtered after it had been prepared and pressed in the ordinary way, and as far as he could judge it was quite free from cocoa matter, so that the nitrogenous material must have arisen from some other source. Cocoa butter was a fat which presented very great difficulties in cooling, because a large amount could be kept for 12 hours after it had reached air temperature without any sign of solidification occurring. It assumed a granular appearance very readily. When the most complex of cocoa butters was broken up it was easy to see the granules which Mr. Allan had described. When a sample of cocoa butter was broken open, even though it was only a small piece of a block, fine drops of water could be seen in some of the vesicles, but a portion which was not in the granulated form contained only a trace of moisture. The ash of cocoa butter was practically nil.

Miss BATTEN, replying to a question asked by Mr. Easton, said that they had used about 10 grms. of agar to 500 c.c. of prune juice, that having been prepared from one pound of prunes.

CIDER APPLE JELLY.

BY B. T. P. BARKER.

After the outbreak of war in 1914 one of the chief objects on which the attention of those engaged in agricultural research was focussed was the avoidance of waste of any agricultural material of food value. The cider apple crop that season afforded a particularly good example for study, since the yield was heavy, and the price of cider apples so low that thousands of tons of fruit were wasted because the farmers did not consider it sufficiently profitable to gather. During September, 1914, the basis of the method of converting this fruit into a palatable product for human consumption, which is described

in this paper, was worked out: but the occasion for utilising it on a commercial scale did not arise until 1917. The manufacture of the jelly was organised by the Bristol University Research Station at Long Ashton, where most of the actual work was carried out.

The immediate object of the work was to utilise for human consumption the 10% or so of sugar (approximately $\frac{1}{2}$ invert sugar and $\frac{1}{2}$ sucrose) in the fruit. The most satisfactory plan proved to be the production of a form of apple jelly by concentration of the juice without the addition of sugar. With cider fruit fetching 20s. per ton and less, a cheap and palatable jam substitute was thus produced.

Cider apples may be divided into three main groups:—(a) sour, (b) sweet, (c) bittersweet. The sour is distinguished from the other two classes by their relatively high content of malic acid, the amount in the average case well exceeding 0.45% of acid in the juice. The acidity of sweet and bittersweet apples is normally much below that figure. The only difference of importance between the two latter classes is that the bittersweets contain appreciable quantities of tannin, which occurs only in very limited quantity in the sweet varieties. For present purposes these two classes may be treated as one, since their mode of use from a food point of view is identical.

Hitherto it has only been the sour varieties which have been drawn upon to any extent to make good any deficiency in the crop of ordinary table apples. Their utilisation presents no difficulties, the quantity of acid contained being sufficient to furnish the necessary cooking qualities for culinary purposes, and the "setting" or "jellying" properties for jam-making. Arrangements were therefore made in the West of England for the 1917 season to deal extensively with this class of fruit for the production of apple pulp for jam-making, and the major portion of the apples pulped at the respective centres organised there as well as those despatched to other stations in other parts of the country were of this type.

The other types, however, have not been utilised previously to any extent on a commercial scale for food purposes, and the work in this direction which has been carried out during the 1917 season must, therefore, be regarded as largely of an experimental character. The form of product which it was decided to make was the type of apple jelly evolved as the result of experiments carried out at Long Ashton in 1914.

Method of making jelly. The general method of making the jelly has already been outlined. The actual details of the process, as generally carried out, are as follows:—

The fruit to be dealt with should consist mainly of sweet or bittersweet varieties or a mixture of both types. A limited proportion of sour apples in the mixture is permissible, but it should in no case exceed one-third of the total quantity, and not more than one-sixth should be allowed if the jelly is made without added sugar. The object is to secure that the percentage of malic acid in the finished jelly shall be between 1 and 1.5%. The exact amount desirable is a matter of taste; for most palates, an amount below 1% results in a jelly too insipid and sickly sweet in flavour, while anything exceeding 1.5% is too sharp. It is obvious that the degree of acidity requisite in the unconcentrated juice must depend upon the extent to which the concentration is to be carried, *i.e.*, upon the percentage of sugar. Approximately 65% of total sugar is needed in the jelly: hence the quantity of sugar in the juice before evaporation, whether natural sugar only, or natural *plus* added sugar, determines the extent of concentration required. At Long Ashton it was the practice to test the acidity and the sugar content of every lot of juice used, adjusting the acidity to the

calculated quantity needed by the addition of sharper or less acid juices as the case might be.

Natural apple juice in an average season contains about 10% of total sugar. The juice, therefore, must be reduced to about $\frac{1}{3}$ of its original volume, if no other sugar is added. It is found in practice more economical to add approximately the same amount of sugar as occurs naturally in the juice. The extent of concentration required is then reduced by one-half, a larger yield of jelly is obtained from a given weight of fruit, and there is a considerable saving of time. The quality of the jelly is also considered by most people to be superior. The added sugar may be either cane sugar, glucose, or corn syrup. In most cases during the past season a mixture of equal parts of cane sugar and corn syrup was used and gave very satisfactory results.

The requisite plant for jelly-making consists of a mill and press, for extraction of the juice from the fruit, and an evaporator, for the concentration of the juice.

Mills and presses. Ordinary cider mills and presses serve perfectly well. At Long Ashton an American type of "grater" mill and a hydraulic press, used at the Research Station for cider-making, were available. The yield of juice per ton of fruit with these machines averaged 150–170 gallons according to the period of the season.

Evaporators. It has been possible as a result of the season's working to obtain important information as to the most efficient type of evaporator for this particular purpose. The simplest form is the ordinary steam-jacketed jam-boiling pan. This is the least satisfactory type of apparatus, since it is not a continuous working form, and the whole of the juice dealt with in one operation has to be subjected to a high temperature until the volume is reduced to the required point. This involves a relatively long period of cooking with consequent partial caramelisation of sugar and, therefore, considerable darkening of colour and the acquisition of a more or less distinct burnt flavour. The "setting" property of the jelly is to some extent affected. The process is also comparatively slow. The usual type of steam-heated vacuum boiling pan is an improvement, but is also open to the objection of not being continuous in its working. Caramelisation is, however, considerably reduced, and colour and flavour accordingly are improved. The speed of evaporation is increased, but the output does not reach that of a continuous working apparatus.

Another type of evaporator used was one constructed on the lines of certain American juice evaporators. It consists of a long narrow wooden trough divided into two compartments by a partition. The two compartments are entirely separated from each other by this at one end, the fresh juice being fed into the one division at this end and the outlet for the concentrated juice being situated at the corresponding point in the other compartment. The two compartments communicate at the far end, where the partition does not extend quite the full length of the trough. The bottom of the trough is made slightly sloping so that the incoming juice flows along the first compartment to its point of communication with the second, and thence returns along the latter to the outlet. Three copper steam pipes are fixed just above the floor of the trough in each compartment, and these are heated by steam at 80 lb. pressure. By regulation of the rate of feed of juice the desired degree of concentration is obtained. A wooden cover is fitted over the whole trough and a central flue to carry off the evolved steam from the boiling juice is provided. This evaporator has the advantage of being continuous in its working, but proved to be difficult to regulate. Variations in steam pressure affected the rate of flow to such an extent that constant attention was required, and a number of other causes contributed to produce such serious

Irregularities in the flow that occasionally the steam pipes near the outlet would become partially uncovered, leading to burning of the concentrated juice, while at other times juice incompletely evaporated would be delivered. It was with great difficulty, therefore, that anything approaching uniformity in the product was obtained. The speed of the apparatus proved to be much slower than had been anticipated, and the cost of concentration was accordingly relatively high. The quality of the product was, on the whole, fair; the colour was generally rather too dark and the flavour at times indicated traces of burning. The jelly as a rule set moderately well, but showed a tendency to be hygroscopic, and during damp periods in December liquefied somewhat. Under drier conditions this is now setting again. The principal drawbacks of the apparatus are the slow rate of output, the high cost for concentration, and the difficulty of securing uniform working.

The apparatus mainly used at Long Ashton was the Kestner evaporator. In essentials, it consists of a continuous series of copper tubes, on the interior surface of which the juice travels as a thin film. The tubes are heated externally by steam under pressure, and the juice in its passage through them is gradually concentrated. The most suitable pressure found during the past season's working with apple juice was about 30 lb. A special arrangement at the delivery end of the tube system provides for the separation of the evolved steam from the concentrated liquid. The machine is a continuous working one. It can be operated with the treated liquid under ordinary or reduced pressure. No vacuum pump was provided for the first season's trials at Long Ashton, and consequently the whole of the work was done under ordinary pressure: but there is no doubt that the reduced pressure would give decidedly superior results as regards quality of product, rate of output, and cost of evaporation. For future work in this direction it is likely to be adopted. Another improvement which should in future be incorporated is to pre-heat the juice before it enters the evaporator by means of the steam given off by the juice.

Condition of juice. Experience in the making of cider has shown that the yield of juice is determined by the condition of ripeness of the fruit at the time it is milled and pressed. Both unripe and over-ripe fruit—particularly the latter—yield less juice from a given weight of apples than fruit which has reached a well-ripened condition. The "setting" quality of the juice is similarly much affected by the state of ripeness of the fruit. The juice from unripe or much over-ripe fruit sets less well after concentration than that from perfectly ripe apples. Up to a point a certain amount of over-ripeness may assist rather than hinder "setting," and it is probable that the fruit should be left over to a somewhat more advanced state of maturity than is desirable from the point of view of yield of juice, if the maximum "setting" quality is aimed at. It is preferable, therefore, that the fruit should be thoroughly well matured before extraction of the juice, even if a portion is distinctly over-ripe, rather than it should be milled unripe, unless steps are taken to ensure good setting by the use of pectin extract, concerning which information is given below.

Extraction of juice. There are no points of particular importance in connection with the extraction of the juice which require notice. The methods found most satisfactory in cider-making apply equally in this case.

Supplies of juice. In preparing quantities of juice for evaporation it is desirable to provide at one time no more than is required for one day's working of the evaporator. Juice more than 24 hours old is liable to show the beginnings of fer-

mentation, particularly during the warmer parts of the season, and, when this occurs, its "setting" qualities suffer owing to changes in its pectin constituents. An attempt was made to overcome this difficulty by treating the juice with sufficient sulphur dioxide to arrest fermentation for a few days: but, although the juice can be retained fit for jelly-making in this way even for so long a period as a fortnight or more, the jelly does not set readily and the method cannot be recommended except for emergencies caused by an over-supply of juice. At the same time it is desirable to provide at the start of each day a sufficient bulk of juice to last throughout the day. If this is pumped into one large vat, it ensures that the whole of the day's output is uniform in character. At Long Ashton two blending vats, holding about 750 gallons each, were used, the contents of the two sufficing to keep the evaporator running for a working day of about 15 hours.

Standardising acidity of juice. The acidity of the supply of juice provided is brought to the required standard by blending as already described. It has been shown that this standard is determined by the degree to which concentration is to be carried, *i.e.*, according to whether sugar is or is not added. As mentioned in the beginning of this paper, the method found most advantageous is to raise the content of total sugar in the unconcentrated juice to approximately 20% by the addition of cane sugar or corn syrup or a mixture of both, in which case the standard of acidity is taken as about 0.35% of malic acid and concentration is carried to about $\frac{1}{4}$ of the original volume.

Use of sugar. When supplies of sugar in some form are available, its use is advised for the reasons already given. If cane sugar is exclusively used, the flavour of the jelly is sweeter and its consistency generally firmer. Corn syrup alone, consisting of a mixture of glucose, maltose, and dextrin, yields a less sweet article, and there is a tendency for the jelly to be more sticky or treacly. A mixture of cane sugar and corn syrup in equal parts gives results little, if any, inferior to cane sugar alone.

Jelly made without added sugar is more intense in flavour, its colour is deeper, and particular care to avoid caramellisation during the making is necessary. It is, however, possible to make a palatable article without added sugar; but the yield of jelly from a given weight of fruit is considerably less, and when the price of apples is about £3 per ton or upwards the cost of the jelly works out at a slightly higher rate than when sugar is added. The latter point simply resolves itself into a question of relative prices of apples and sugar.

It is better to add the sugar before than after concentration of the juice, since, although more steam is required for concentration, it is not easy to dissolve the sugar and obtain an even mixture in the thick, syrupy, concentrated liquid.

Use of pectin extract. The investigations on pectin compounds which have been conducted at Long Ashton during the past four years have shown that the following three conditions are necessary for a proper "gel" formation, *viz.*, (a) the content of total sugar present in solution—whether cane sugar, glucose, or some other suitable carbohydrate, either singly or in mixture—must approach 60–65%; (b) an acid of some kind, preferably malic, citric, or tartaric acid, must be present in quantity approximating at least to the equivalent of 1% malic acid, and (c) a suitable form of pectin must also be present in quantities of 0.5% or upwards. In many samples of apple juice dealt with in the course of this work, with the acidity raised to the standard adopted as being most suitable for jelly-making, these three essential conditions were easily obtained in the finished product when the fruit handled was in reasonably uniform condition as regards ripeness and was milled when well ripened.

Even when the fruit was somewhat over-ripe no serious trouble was experienced; but badly over-ripe fruit as well as unripe or unevenly ripe samples caused uncertain results, mainly on account of pectin deficiencies. Since in practice the condition of the fruit generally is very variable, it was considered advisable during the greater part of the season to add a limited quantity of a pectin extract to the juice before evaporation.

The extract was made by passing waste steam from the evaporator into a mass of pressed apple pomace, plentiful supplies of this being available. After being steamed for some time, the mass was placed under the press and as much liquid as possible extracted. This fluid, which was thick and mucilaginous and contained considerable quantities of pectin, was added to the juice at the rate of 15 gallons of extract to 100 gallons of juice. When this method was adopted, the jelly could be relied upon to set well, provided that the juice was not over-cooked in the evaporator. With the extract an additional quantity of sugar was used (15 lb. of sugar to 15 gallons of extract) to avoid dilution of the juice in respect of that constituent.

The use of a crude pectin extract prepared in the manner described is mainly for the purpose of ensuring the proper "setting" of the jelly; but it also affects the yield from a given weight of fruit. Practically it amounts to the addition of 15% to the volume of the fresh juice handled with a corresponding gain in the final amount of jelly. It occasionally results in a still greater increase in the yield of jelly, since some juices without it have to be concentrated to a smaller bulk than that normally requisite in order to give a sufficiently firm "set."

Some preliminary experiments with an improved form of pectin preparation suggest that an appreciable reduction in the cost of production should be possible, provided that the value of sugar as compared with that of the fruit does not vary materially from the ratio obtaining during the 1917 season. The preparation in question also promises to simplify the problem of making the jelly set and to yield a superior product.

The addition of the pectin extract does not reduce the strength of the flavour to an appreciable extent. The acidity is slightly reduced, but this can be adjusted by modifying the standard of acidity in the unconcentrated juice by suitable blending.

Clearing of juice. The fresh juice as it is received from the press is a turbid liquid containing variable amounts of particles of apple pomace in suspension. The removal of the coarser particles is essential and is readily accomplished by straining the juice, as it is pumped into the blending tank, through a filter bag made of canvas or other suitable material of moderately fine mesh. By that means the juice, while still turbid, is freed fairly completely from suspended solid matter, the turbidity being mainly caused by pectin compounds in solution. A further filtration of the juice is arranged as it is fed to the evaporator, the end of the suction hose of the supply pump being covered with fine-meshed straining cloth.

The turbidity of the juice disappears almost entirely in the final stages of its concentration in the evaporator. This is believed to be due to the interaction of the sugar, acid, and pectin contents, and the comparatively sudden change from opacity to relative transparency which occurs apparently at or about a given point of concentration is regarded as indicating that the "jellying" stage has been reached. In practice it constitutes a safe guide.

The jelly prepared in this way without more elaborate attempts at clearing is semi-transparent when cold, a certain amount of haziness developing as it cools.

Concentration of juice. A supply pump provides a continuous flow of juice into the evaporator, the rate of which can be regulated as required. This is determined by the specific gravity of the concentrated juice. It is considered necessary that the jelly should possess a total sugar content of 60–65% to ensure adequate keeping and setting properties. This is equivalent to a specific gravity of 1.35 at 15° C., which corresponds to about 1.3 at the temperature of the concentrated liquor as it is collected from the evaporator (about 95° C.). The whole rate of working of the apparatus is therefore controlled by the specific gravity of the concentrated juice. This is taken at frequent intervals with a hydrometer, the standard gravity adopted being 1.3 for the hot liquor. When the gravity reading is too low the rate of supply of juice to the evaporator is slowed down, and when it is too high the supply is increased. Another means of controlling the rate of concentration is to regulate the steam pressure of the evaporator. By the combination of this method with that of regulation of the supply of juice, it is not difficult with the Kestner apparatus to maintain the specific gravity of the concentrated liquor at any point required. Control is similarly obtained with the American type of evaporator, but exact regulation is more difficult, and closer and continuous attention is needed in this case.

Output. As regards output the Kestner evaporator at Long Ashton was capable of dealing with 100 gallons of the prepared juice per hour under fair average conditions of working, giving an average production of about 275 lb. of jelly per hour. Under specially favourable conditions the quantity of juice per hour used advanced occasionally to 110–120 gallons. These figures refer to cold juice only. In a trial where the juice was preheated to 75° C. before entering the evaporator, the juice supply per hour easily reached 125 gallons. Probably an appreciable increase in these figures would have been recorded had a larger steam boiler been available. That used had to be run at full capacity the whole time in order to maintain the steam pressure in the evaporator near 30 lb. per sq. inch.

ANALYSIS OF COMMERCIAL SACCHARIN. THE ESTIMATION OF O-BENZOYLSULPHONIMIDE FROM THE AMMONIA PRODUCED BY ACID HYDROLYSIS.

BY H. DROOP RICHMOND, F.I.C., AND
CHARLES ALFRED HILL.

THE present investigation was undertaken with the two-fold motive of finding a more rapid method of estimating o-benzoylsulphonimide and of eliminating from the known methods those factors giving rise to a variation of results obtained by different workers.

The principal known methods take from 3½ to 4 hours to complete, and in a factory engaged upon the manufacture the reduction of this time is a matter of considerable importance, while we have found variations as great as 4% by the same method due to personal factors.

The methods commonly employed are applications of the principle established by Remsen and Burton (Amer. Chem. J., 11, 463) and Hefehmann (Pharm. Centr. Blatt., 85, 105) that saccharin is hydrolysed by weak acids to o-sulphonaminobenzoic acid and ammonium sulphobenzoate and depend upon the determination of the ammonia; the former employed 1.25N hydrochloric acid and the latter 70% sulphuric acid as the hydrolytic agent. Reid (Amer. Chem. J., 1899, 461) studied both these methods in detail, and finally gave preference to the use of hydrochloric acid, which he found under the conditions he prescribed to convert saccharin completely into the ammonium salt of

o-sulphobenzole acid, while *p*-sulphonaminobenzoic acid and *o*-toluenesulphonamide, the two impurities most commonly present in commercial saccharin, were unaffected. His directions were:—Boil 0.65 gm. of saccharin with 50 c.c. of 1.2*N* hydrochloric acid for 2 hours in a small flask fitted with an air condenser, evaporate to 10 c.c., and distil off the ammonia into standard acid (minor details here omitted). This method was tried by Reid on pure saccharin and mixtures of known composition, and found to give excellent results, but probably the fact that the final evaporation is a little troublesome has prevented its general adoption. Proctor (Chem. Soc. Trans., 1905, 242) simplified Reid's method by omitting the final evaporation, boiling for 2½ hours, and reducing the strength of the acid to approximately normal; unfortunately he does not appear to have tested this modification against mixtures of known composition, and, as we shall show, the reduction of the strength of acid, and the want of more exact definition of conditions is responsible to a considerable extent for the discrepancies between analysts.

Proctor's modification was so obviously convenient that it has been largely adopted, but we have found that his use of the words "approximately normal" in the description of the method has been interpreted by different analysts who have given us their detailed working directions as a strength varying from 1.2*N* to 0.7*N*.

Testoni (Z. Unters. Nahr. Genussm., 1909, 18, 577) heated the saccharin with 5*N* acid for ½ hour in an autoclave, a method which lacks convenience.

Hefelmann's method of heating with 70% sulphuric acid in a water bath for from 2 to 4 hours has been adopted by the B.P., but only as a qualitative test, and was found by Reid to give very fair results. A modification of this worked out in these laboratories consists in boiling 0.6 gm. saccharin with 10 c.c. of 70% sulphuric acid for a short period (not exceeding one minute), pouring at once into a considerable quantity of cold water, and distilling off the ammonia. This method has the advantage of great rapidity, but at the same time, unless the conditions are narrowly defined and adhered to, is liable to give high results with impure saccharin, and is consequently, as we have found, unreliable except in skilled hands.

All the above methods depend on the comparatively rapid hydrolysis of saccharin by acids to an ammonium salt, and the estimation of the ammonia, and do not discriminate between *o*-benzoylsulphonamide and *o*-sulphonaminobenzoic acid, which owing to its considerable solubility in water is a possible but not likely impurity in appreciable amount.

Testoni (*loc. cit.*) has devised a method depending upon the insolubility of the silver salt in alcohol, Proctor (*loc. cit.*) discussed the conversion into salicylic acid by fusion with alkali, and there are numerous methods which depend on the estimation of the sulphur, but these methods are of little use in the examination of commercial saccharin. Gnädinger (J.A.O.A.C., 1917, 11, 1, 25) has studied the solubility of saccharin in various solvents.

According to work of Remsen and Burton (*loc. cit.*), the following reactions take place on hydrolysing saccharin with acids:—

In the presence of a large and constant excess of hydrogen ions, both reactions will be approximately unimolecular, and the results should approximately agree with a formula of the type

$$1-x = \frac{K_2}{K_2 - K_1} e^{-K_1 t} - \frac{K_1}{K_2 - K_1} e^{-K_2 t}$$

where *x* is amount of saccharin converted into ammonia; total=1; the minus sign comes from the fact that the first stage is a conversion of saccharin into the ortho acid, while the results are expressed in terms of the formation of ammonia from the ortho acid.

It is evident that Reid's method, involving a change of conditions during the experiment, would not lend itself to a study of the mechanism of the reaction, and it was found that in Hefelmann's method the solution of the saccharin was slow and the time, therefore, could not be accurately determined, but Proctor's modification appeared to be carried out under fairly constant conditions, and our first experiments were a study of the ammonia produced in different times of heating. Our procedure was as follows:—

0.6104 gm. of saccharin was placed in a flask, and 50 c.c. of *N*/1 hydrochloric acid, just raised to the boiling point, added; the saccharin was dissolved in a very short time, and the solution boiled under a reflux condenser for the stated period; the time was, of course, not accurately known, though the error was small; the temperature was not quite constant, as we frequently had evidence of superheating, followed by explosive ebullition, and the concentration would vary slightly in different parts of the solution, but it was hoped that the conditions would be sufficiently constant to enable us to verify the equation given above. The saccharin was prepared from a fairly pure commercial saccharin, by dissolving in slightly less than the calculated quantity of sodium bicarbonate, adding acid equal to 10%, allowing this to crystallise out, and then precipitating about 80% of the remainder; this treatment was repeated, and the resulting product crystallised from acetone (*cf.* Pope, J. Chem. Soc., 1895, 985). It had a melting point of 229° C. The *p*-sulphonaminobenzoic acid was twice recrystallised from hot water, the melting point of the product of the first and second crystallisations being 288° C. The *o*-toluenesulphonamide was also carefully purified and had a melting point of 153.2° C. Unfortunately we found that duplicates gave values differing by a considerable amount, and we have therefore only calculated approximately the constants in the equation as $K_1 = 0.0414$ and $K_2 = 0.0828$, and the agreement between those and our experimental results is sufficiently good to show that the mechanism of the reaction is probably that stated above. Two series were carried out with *N*/1 acid, one with pure saccharin, and the other with a commercial article of which the probable content of saccharin was 97.2%; the 2*N* and 3*N* series were carried out with good commercial products. From the results with 2*N* acid it is evident that if the time is multiplied by 2.0 the results agree closely with those obtained by the use of *N*/1 acid, showing that the same law is followed, while with 3*N* acid the agreement is on the whole good if the times are multiplied by 2.5. A series in which saccharin was hydrolysed by boiling with water at a strength of *N*/15 took approximately 12 times as long to reach the same figures in the early stages as the *N*/1 series.

Time	100% product.	<i>N</i> /1 HCl		2 <i>N</i> HCl		3 <i>N</i> HCl	
		97.2% product.	Calc.	Calc.	Calc.	Calc.	Calc.

480 "	99.7	—	100.0				

The rate of hydrolysis is fairly proportional to the strength of acid, though slightly higher with weak acids, and lower with higher strengths. This is shown graphically in the accompanying curve, plotted from the figures in the above table.

It would appear, therefore, that the use of Proctor's method, adhering strictly to normal acid, will give results from 0.5 to 1.0% low; if the wording "approximately normal" is taken to mean 1.2N they will be nearly correct, while if the strength is reduced to 0.7N and the solution boiled for three hours, they will be about 2% low. Further, owing to slight but unavoidable variations of temperature, concentration, and time of effective heating, any method which does not give approximately complete hydrolysis is liable to a fairly large experimental error, and the following are the minimum times of heating which can be depended upon to hydrolyse saccharin with practical completeness.

Strength of acid.	Time in hours.
0.7N	5
1.0N	4
1.2N	3.3
1.5N	2.5
2.0N	2
3.0N	1.5

We have made some experiments on the influence of temperature by hydrolysing saccharin for 2 hours on days when the barometer varied, and these indicated that the reaction follows the usual law of doubling for a 10° C. rise.

It is seen that the rapidity of the method can be increased by increasing the strength of acid; it is evident that as the reaction proceeds in two stages, the first one of which is the slower, any method of increasing this would add to the total speed. It is known that alkali hydrolyses saccharin very rapidly to *o*-sulphonaminobenzoic acid, the action stopping at this stage; our experiments showed that on adding 10 c.c. of 7.5N sodium hydroxide to 0.6104 grm. of saccharin, raising to boiling, cooling, and making neutral, the sweet taste had disappeared, indicating that the first stage of the reaction was over, and we also found that no ammonia was given off on continuing the boiling for 10 minutes. We therefore made a series of experiments by adding 10 c.c. of 7.5N sodium hydroxide to 0.6104 grm. of saccharin, raising to the boil and boiling for 2 minutes, cooling somewhat, adding 15 c.c. of 10N hydrochloric acid (B.P. strength), and boiling under a reflux condenser for various times. As there is only one reaction taking place, the formula for bimolecular reactions should express the results. A commercial saccharin was used in this series. The following were the results, together with those calculated by the formula $1-x = e^{-0.0161t}$:

Time.	% Hydrolysed.	Calc.
5 minutes ...	55.2	55.3
10	81.8	80.1
15	93.3	91.1
30	97.2	99.1
45	99.9	99.9
60	99.5, 99.7	100.0
120	100.2	100.0
240	100.4	100.0

The calculated results, which agree moderately well, show that approximately 16% per minute is converted by acid hydrolysis.

We have adopted as working conditions 2 minutes' boiling with 10 c.c. of 7.5N sodium hydroxide, taking care not to concentrate appreciably, followed by 50 minutes' boiling after the addition of 15 c.c. of 10N hydrochloric acid under any form of reflux which condenses efficiently without retaining an appreciable amount of liquid, adding a little powdered pumice if desired to promote steady boiling; sodium chloride should not be deposited whilst the liquid is boiling. No correction for variation of temperature due to the usual changes of barometric pressure (740—775 mm.) is necessary. After the heating is completed the liquid is cooled, 75 c.c. of cold water added, and a current of air passed through the upper part of the flask to remove any acid vapour; 15 c.c. of 7.5N sodium hydroxide is added carefully, and the flask at once connected with a distillation apparatus provided with an efficient steam trap, a condenser, and an absorption flask in which is placed 20 c.c. of N/5 hydrochloric acid. The distillation is started with a small flame to obviate a considerable rush of air through the standard acid, which would be liable to lead to incomplete absorption of the ammonia; after the air has ceased to bubble through the acid the flame is raised and about 70 c.c. is distilled. The solution is titrated with N/10 alkali, using methyl red as indicator, and corrected for a blank test of the reagents. Other indicators may be used, but we prefer methyl red as being the most delicate. No correction is needed for the small amounts of ammonia present in commercial saccharin (not usually exceeding 0.01%), as this is practically all removed by the alkaline treatment. The strengths of the acid and alkali used should not vary more than 2% at most from those given above. With 0.6104 grm. of saccharin the number of c.c. of N/10 acid neutralised multiplied by 3 = percentage of saccharin.

The following test experiments were made with mixtures of carefully purified saccharin, *p*-sulphonaminobenzoic acid, and *o*-toluenesulphonamide.

Saccharin.	Calculated composition.			Saccharin found, %.
	<i>p</i> -Compound.	Amide.

It is seen that while our alkaline-acid method gives good results, averaging about 0.1% high, Proctor's method averages 0.8% low. In both methods, especially in the alkaline-acid process, there is a slight hydrolysis of the para acid and the amide, the amide hydrolysing the more easily, but the amount hydrolysed is negligible in commercial saccharins.

The following table shows the results with the sulphuric acid methods; the Hefelmann method was carried out by heating 0.6104 gm. with 10 c.c. 70.5% sulphuric acid in a tube immersed in a briskly boiling water bath for 3 hours, stirring vigorously from time to time, and the $\frac{1}{2}$ -minute method by boiling 0.6104 gm. with 10 c.c. of 70.5% sulphuric acid, heating to boiling in from 1 to 14 minutes and boiling for $\frac{1}{2}$ minute, and then pouring at once into 75 c.c. of cold water. The temperature in the Hefelmann method is probably a degree or two below 100°, and that of boiling 70.5% sulphuric acid about 160°C., but both are liable to slight variation.

% Saccharin.		p-Compound.		Amide.		Saccharin found.	
						Hefelmann	$\frac{1}{2}$ -minute.
99.5	—	—	—	—	—	99.5, 98.5	99.4
94.5	—	—	—	—	—	94.3, 93.8	94.4, 92.6, 94.4
60.0	39	—	—	1	—	59.6	66.5
0	100	—	—	0	—	2.0	7.4
0	0	—	—	100	—	9.8	37.5, 38.4

A number of comparisons between the Proctor and $\frac{1}{2}$ -minute methods showed that the results with the latter were about 1% higher than with Proctor's method on saccharins containing 90% and upwards of o-benzoylsulphonamide, and quite low in amide.

These results indicate that the sulphuric acid methods are of approximate accuracy only, and we are in substantial agreement with the criticisms of Reid (*loc. cit.*) on Hefelmann's method; the $\frac{1}{2}$ -minute method has a certain value as a works method, but as we have found that 2–3 minutes' boiling hydrolyses the para acid and the amide practically completely, it requires to be used with great caution.

We are indebted to Miss Florence M. Richards for a number of comparisons between our alkaline-acid method and the Proctor method, illustrating the lower results by the latter; the average difference was 0.6%.

Conclusions.

1. Reid's hydrochloric acid method is accurate, but rather troublesome.
2. Proctor's modification tends to low results; it is insufficiently described and leads to discrepancies between analysts. By increasing the time to 4 hours or the strength of acid to 1.5N it becomes reliable.
3. Our alkaline-acid hydrolysis method is rapid, convenient, and accurate, and as it eliminates the ammonia correction saves working time.
4. The sulphuric acid methods are not so good as the hydrochloric acid hydrolysis; the $\frac{1}{2}$ -minute method is a very rapid approximate method, but requires to be used with caution.

This work was done in the analytical laboratory of Messrs. Boots Pure Drug Co., Ltd., to whom we wish to express our thanks.

COLLOIDAL ELECTROLYTES: SOAP SOLUTIONS AS A TYPE.

BY JAMES WILLIAM McBAIN.

Soaps are substances of definitely known and simple composition, but their mixtures with water exhibit a remarkable variety of pronounced characteristics. They resemble in many of their properties a very large group of substances of great industrial importance, such as the dyestuffs, gelatin, and protein salts; these, however, are mostly of less simple chemical constitution.

During the six years preceding the outbreak of war, extensive and accurate measurements were carried out in this laboratory with regard to some of the fundamental properties of soap solutions.* These have led to a comprehensive theory of solutions of such substances which we define as colloidal electrolytes. To this group we expect many inorganic substances will belong, in addition to most organic materials containing eight or more carbon atoms which are capable of splitting off an ion of any kind, or even of taking up one of the ions of an added electrolyte. Even in non-aqueous solutions similar phenomena appear to be of frequent occurrence, and one such case has been studied in order to show how the otherwise typically anomalous results are explained.

The hypothesis to which we have been forced is that all these solutions are salts in which one ion is replaced by an ionic micelle which exhibits high conductivity and great solvation, and which carries a large number of electrical charges. Extensive changes result from alteration in the concentration, so that on the one hand, great dilution may result in the nearly complete formation of simple electrolyte, and, on the other, high concentration or the addition of other substances may lead to the quantitative formation of neutral colloid.

In previous communications it has been shown how the conception of such an ionic micelle of great valency and hydration explains the really high conductivity and great mechanical viscosity at the same time, the proof being based on a simple application of the underlying principle of Stokes' law. The experimental data have further fully established the important theoretical result that colloids, colloidal electrolytes, and electrolytes may participate in true perfectly reversible and reproducible equilibria. This is the case in all soap solutions in which the conditions are defined.

Summary of the constitution of soap solutions.

Commencing with the case of very dilute solutions, the soaps are partially hydrolysed according to the following equation:—

The acid soap is in suspension, either coarse or colloidal as the case may be, and it consists of something between the neutral salt NaR and the acid soap NaHR₂, where R is the radical of the fatty acid. Only excessively minute amounts of free fatty acid can exist as such in any soap solution, even when a whole equivalent excess of fatty acid has been added, so that the equation just given must supersede the ordinary statement of textbooks and other publications. The data which establish this are based upon analysis, conductivity, measurements of electromotive force, and measurements of the free hydroxyl ion by the rate of catalysis of nitrosotriacetaminine (see Francis, p. 252 T).

Faraday Soc., 1913, 9, 99; McBain and Salmon, J. Amer. Chem. Soc., 1918.

In decinormal solution or somewhat less, soaps are chiefly composed of simple electrolyte in true solution, with simple ions. Hydrolysis is still present, but only in a very minor degree, since the hydroxyl ion concentration is shown by the two methods just cited to be only about $N/1000$. As the concentration increases, the fatty ions rapidly coalesce to form the ionic micelles described above, until in $N/2$ or $N/1$ solution the colloidal electrolyte comprises all the soap, hydrolysis being still more insignificant. As the concentration increases the ionic micelle becomes less solvated and conducts even better. The only crystalloidal constituent left is the potassium or sodium ion, as

out the soap in the form of a curd containing some combined water and other sorbed material. An ordinary analysis of such a curd gives but little clue to the composition of the solid part of it, since it is a heterogeneous sponge or felt full of mechanically enclosed mother liquor.

Surprising as it may appear, no data have been published which give information as to how much, if any, of the water and the salts contained in a bar of soap is actually combined in the solid part of the curd, and how much is merely enmeshed. We have established these quantities for several definite cases, and it will be comparatively simple now to extend measurements to all soap curds. This

even the undissociated soap is now entirely in the form of colloid. Alcoholic solutions differ entirely in their behaviour, as the soap is a simple unhydrolysed electrolyte throughout.

The true composition of soap curd.

With increasing concentration the dissociation of the colloidal electrolyte decreases, and the composition of the micelle (which being colloidal sorbs, i.e., adsorbs and absorbs, most of the available materials, including probably the neutral colloid) approaches that of neutral colloidal soap. Mere increase of concentration probably never makes this process complete, but it is rapidly effected by the addition of salts of any sort, which in sufficient concentration quantitatively salt

is well known to be an important practical problem for the manufacturer. In the case of sodium palmitate, for example, salted out at 90° C. by a saturated solution of common salt, the combined water amounts to $NaP + 2.1H_2O$, which corresponds to 88.0% soap. There is a good deal of enmeshed water even in the best household soaps. The quantitative data will be communicated later.

The hydrolysis of soap solutions.

All soap solutions contain free hydroxyl ion. The only measurements of this so far published are contained in the work of McBain and Martin by the method of electromotive force, and of McBain and Bolam by the method of catalysis of nitrosotriacetoneamine. Great diversity of opinion had

previously prevailed as to whether soaps were scarcely or almost entirely hydrolysed. This was chiefly due to the employment of such unsuitable methods as direct titration in order to study this equilibrium, which was bound to lead to arbitrary and erroneous results.

Our quantitative data show that all soap solutions are alkaline, varying from $N/3000$ to $N/300$ for pure soap solutions, down to $N/30000$ for acid sodium palmitate, NaIP_2 . Several per cent. excess of alkali hydroxide is required to drive back this slight hydrolysis completely, but, even in the presence of large excess of alkali, not more than a few per cent. of this alkali can be sorbed by the soap. This means that the hydrolysis must be approximately equal to the alkalinity.

The highest soaps are the most alkaline, and the alkalinity is less at lower temperatures until the solution becomes heterogeneous, whereupon the alkalinity increases several fold. The alkalinity is less in the presence of moderate amounts of salt. Probably for these reasons, commercial soaps are all less alkaline than sodium palmitate. Since soaps are never used except in solution, and since free alkali is often injurious to the skin, this question of alkalinity is one that is of direct personal interest to many of us.

It has long been known, especially since the brilliant investigations of Spring, that the alkalinity of soaps has but little to do with their washing power. This property is due entirely to the colloid which is present.

In very concentrated soap solutions the hydrolysis diminishes with abnormal rapidity. This is probably due to the palmitate ions, the subjects of this hydrolysis, having disappeared to form ionic micelle.

The conductivity of soap solutions.

Some years were spent in this laboratory in obtaining accurate data for one of the higher soaps, and no effort was spared to eliminate and control all sources of error. Since then we have accumulated a mass of data for all the pure soap solutions and for a few mixtures. Other determinations in the literature, mostly published since McBain and Taylor's work, are in substantial agreement, although in some cases the experimental difficulties appear not to have been completely overcome. Some of our results are given in Tables I.—III., in which concentrations are expressed in gram-equivalents of soap per 1000 grms. of water.

The results in these tables show the strikingly anomalous form of the conductivity curves of the higher soaps and also their magnitude as compared with the acetates, the nearest true salts. Sodium and potassium soap solutions are very similar (see the curves given by Bunbury and Martin, Chem. Soc. Trans., 1911, 105, 421).

It is beyond question that soaps exhibit a high proper conductivity, and that this is abnormally high in concentrated solutions. In the case of the higher soaps the conductivity, after passing through a minimum at about $N/10$, rises with increase of concentration up to nearly $N/1$ solution. This is in excellent agreement with the hypothesis of an ionic micelle of conductivity intermediate between that of sodium and potassium ion, which was deduced from other considerations. The replacement of the comparatively slow large true ion by the more highly conducting micelle, and the final gradual falling off in the concentration of the latter as the concentration of the solution is still further increased, are exactly mirrored in these curves. It would be difficult to find another explanation for them.

The osmotic properties of soap solutions.

It is surprisingly difficult to determine the osmotic behaviour of soaps by any of the usual methods.

We were able to show that the boiling point method is useless, likewise the lowering of vapour pressure, on account of the unavoidable presence of enclosed air. The osmometer methods are obviously useless for a system in which there is an equilibrium between colloidal and crystalloidal forms of the same material, unless a strictly semi-permeable membrane could be found for the purpose.

Together with Mr. Salmon, I devised a dew point method of measuring the "molecular weight," and obtained data for about one hundred soap solutions. This method is very useful, but it is unfamiliar, and has not been applied before to solutions. Incidentally it may be mentioned that the measurements were extended to soap curds and solid soap, with regard to which data will be published later.

For a very few soaps, by taking special precautions, the freezing point method can be used. This leads to values for only one temperature, but the results corroborate the findings of the dew point method. Of course, the osmotic effect is essentially a measure of the large amount of crystalloidal present. Table IV. gives a few selected data for the amounts of crystalloid thus indicated by these two methods, for 90° and for 0° C.

TABLE IV.
Total crystalloidal material present in soap solutions.

Concentration ..	0.1	0.2	0.5	1.0	2.0

K Oleate at 0° ..	0.049	0.063	0.149	—	—

The first fact about the osmotic data is that the osmotic activity is real, and moderately great. The most interesting conclusions can only be obtained by comparing these data with the conductivity results. The remarkable fact then appears, that in the concentrated higher soap solutions (about C_{12} upwards) the whole of the osmotic activity is required to account for the potassium or sodium ion alone, and even that only on the assumption that the conductivity of the negative carrier (our colloidal "ionic micelle") conducts almost as well as the potassium ion. Thus the potassium or sodium ion is the only crystalloidal constituent of these concentrated soap solutions.

A further study of all the data leads to the conclusion, in conformity with theory, that the solvation of the ionic micelle diminishes with increase of concentration, and thus its conductivity increases. Its formula is probably $(\text{NaIP})_x \cdot \text{P}^{\text{an}}(\text{O})_m \cdot (\text{H}_2\text{O})_n$, where P^{an} is the anion of the fatty acid in question.

The effect of high and low temperature on soap solutions.

With regard to solutions which are clear and approximately homogeneous, a low temperature favours formation of colloid. Further, this colloid is more hydrated than at higher temperatures, as may be seen by reference to Table IV. The various

adjustments in the equilibria involved when a solution is cooled or heated are made very quickly and are very soon complete to within one per cent. This ensures that definite reproducible properties and effects are always obtainable from a soap solution of any particular composition under any specified set of conditions. As long as the soaps are in solution there is very little difference between potassium and sodium soaps except that the former are always more colloidal.

At room temperature, all but extremely dilute solutions of all sodium soaps above the caprylate (C_8) are solid. This solidification withdraws soap from solution and is essentially crystallisation, the mother liquor being mechanically enclosed. Very dilute solutions of sodium soaps are broken down into an aqueous liquid containing some alkali and a trace of soap, and in this are suspended the acid soaps which are the product of hydrolysis.

The potassium soaps solidify at much lower temperatures and they possess a much greater tendency to exist as transparent liquids which are often so viscous as to be almost, or quite, gelatinous. To obtain the same solidification (crystallisation) phenomena as with the sodium soaps, it is necessary to use higher concentrations of the potassium soaps of greater carbon content and to have a much lower temperature. In other words, the potassium soaps are more "soluble" than the corresponding sodium soaps. The soap solutions which readily crystallise can also be more easily salted out by the concentrated salt solutions, though this is an entirely different phenomenon.

It is worth while noting that supersaturation with regard to crystallisation often occurs and may easily be prolonged for years. Inoculation or mechanical shock brings about the solidification to a white solid in a relatively short time. We have only made a beginning with the study of the phenomena of solidification and of salting out, and a considerable extension of this work will be necessary, as it is of direct manufacturing importance.

The viscosity of soap solutions.

We have made only qualitative observations of this property, but other investigations (and in particular one by Kurzmann deserves mention, *Kolloid-Chemische Beihefte*, 1914, 5, 427) have made exact measurements for a series of cases. The viscosity of soap solutions varies enormously, from about that of water up to a value many thousand-fold greater, giving a perfectly continuous transition from thin fluid, through viscous liquids which can be "span," to a very stiff clear jelly. This change, by the way, is not accompanied by any very great change in the electrical conductivity.

The viscosity is increased in very rapid exponential fashion by increase of concentration, lowering of temperature, or rise within the homologous series of the fatty acids. The addition of any electrolyte such as a hydroxide, carbonate, or chloride in small quantities reduces the viscosity slightly through a minimum and then increases it quite enormously. All of these viscosity changes are quite in accordance with the theory of colloidal electrolytes which is described in detail above.

Influence of position in the homologous series.

The appearance, washing power, density, and conductivity of the caproates (C_6) distinctly mark the beginning of that deviation from the behaviour of the acetate, which rapidly and regularly increases through the other members of the homologous series until the typical character of the higher soaps is attained. At the top of the scale is behenic acid (C_{22}) often met with in modern soaps and whose soap solutions solidify at a high temperature. The behenates tend to form nearly undissociated colloid and the solutions often have a distinct structure like those of starch. The

laurates (C_{12}) are perhaps the most interesting, as they are just in the middle of the series, the lowest really good soap in whose solutions by suitable adjustment of concentration most of the typical phenomena of the soaps may be produced. This acid is perhaps the most important constituent of industrial soft soaps. Solutions of the sodium salt are usually solid at room temperature. When liquid they, like those of potassium oleate, are viscous liquids or jellies.

Oleic acid (C_{18} unsaturated) produces soaps *par excellence*. At room temperature the sodium soap solutions are clear. The distinctive behaviour of these soaps is due to the fact that the formation of hydrophilic ionic micelle persists into unusually low concentrations (see for instance Table IV.).

The properties of mixed soaps.

It will be seen from the above summary that we have now for the first time a fairly definite idea of the constituents of soap solutions. With this picture in our minds we are now able; much more extensively than was possible before, to draw upon the knowledge of colloids in general in order to understand and predict the various properties of soaps and their solutions.

Again, although our work of necessity had to be carried out with pure materials, it is now possible to make predictions with regard to various mixtures. This is essential, since commercial soaps are composed of an almost infinite variety of combinations of fatty acids. It is evident from our theory that the behaviour of mixtures is of course by no means additive.

The investigations are still only in their first stages, but it is hoped that the series already completed of laborious and often difficult experiments will have laid a foundation for the elucidation of the industrial and theoretical properties of these very important and interesting substances.

A METHOD FOR THE DETERMINATION OF THE ALKALINITY OF CERTAIN SOLUTIONS.

BY F. FRANCIS.

For several years the catalytic decomposition of nitrosotriacetoneamine, and similar substances, under the influence of hydroxyl ions has been studied in the Chemical Laboratories of the University of Bristol by my students and myself. (*Chem. Soc. Trans.*, 1912, 101, 2358; 1913, 103, 1722; 1915, 107, 1651.)

Substances of this class break down, when acted upon by alkalis, with the evolution of nitrogen and the formation of phorone or its analogues; in the case of nitrosotriacetoneamine itself the reaction may be expressed as follows:—

Although in the case of some of the nitrosoamines and in certain concentrations of hydroxyl ions there appears to be a simultaneous evolution of small quantities of oxygen, this does not interfere with the method.

It was found that the velocity of this decomposition depends on the concentration of hydroxyl ions, and consequently an estimation of the rate at which nitrogen was evolved constitutes a method for the determination of the alkalinity of those liquids in which—owing to colour or for other reasons—it is inconvenient or impossible to carry out the estimation by any of the usual methods such as the use of an indicator or electro-motive force. My colleague, Dr. J. W. McBain, for instance, has used this method for the determination of the alkalinity

of certain soap solutions. The decomposition is that expressed by the unimolecular equation,

$$K = \frac{2.303}{t} \log \frac{P_{\infty} - P_0}{P_{\infty} - P},$$

where P_0 is the pressure reading at the time taken as zero, P is the reading at time t , and P_{∞} the infinity reading. The minute is taken as the unit of time.

The rate of evolution of nitrogen is most accurately followed by pressure readings, and the apparatus and method have been described in detail (Chem. Soc. Trans., 1915, 107, 1653); a much simpler apparatus may be employed and the volume of the evolved gas measured in a burette instead of reading its pressure, although this method is not quite so accurate as the former.

FIG. 1.

Concentration of hydroxyl ions, N .

Catalysis of Nitrosoamines with Small Conc. OH' .

- B. Potassium hydroxide.

minations of the temperature coefficients of these reactions, will be found in the papers mentioned above.

Fig. 1 shows the relationship between the velocity constant and concentration of hydroxyl ions for a

series of nitrosoamines. The dotted portions of the curve indicate that the constants are drifting, and in such cases a mean value has been taken. Since nitrosotriacetoneamine and nitrosovinylldiacetoneamine are more easily prepared than the others, either one or the other of these substances is most suitable for the determination of the concentration of hydroxyl ions up to 0.4N.

The following table summarises the various data for these two substances for small concentrations of hydroxyl ions. It will be noticed that the relationship between velocity constant and concen-

tration of such ions—e.g., $\frac{K}{OH'}$ —in such regions is expressed by a straight line. In the table R is the value for this constant, 1.92 for nitrosotriacetoneamine at 30° C., and 0.171 for the vinyl derivative at 40°.

Nitrosoamine.	Region of OH' concentration.	Value of R .	Range of temp.
Nitroso-triacetoneamine	up to 0.05N	$1.92 \times \frac{t-30}{10}$	30°–40°
Nitrosovinyl-diacetoneamine	up to 0.4N	$0.171 \times \frac{t-40}{10}$	40°–50°

In fig. 1, it will be seen that in the case of all the nitrosoamines investigated, as the concentration of hydroxyl ions increases there comes a point when the constants "drift," on further increase this ceases, and with increasing concentration the velocity constant falls. The following table gives the region of concentration for which the previously mentioned nitrosoamines are suitable:—

Nitrosoamine.	Conc. of OH' at which K commences to drift.	again becomes constant.	Maximum conc. of OH' ions for which nitrosoamine is suitable.
Nitroso-triacetoneamine	about 0.05N	about 0.35N	up to 1.4N for NaOH and KOH
Nitrosovinyl-diacetoneamine	about 0.40N	{ about 1.4N about 1.55N	up to 2.0N for KOH up to 1.55N for NaOH

In higher concentrations a curve of standard results may be made from the data already given (Chem. Soc. Trans., 1915, 1660). Fig. 2 gives the relationship between the velocity constant and high concentrations of hydroxyl ions for the case of

FIG. 3.

Concentration of hydroxyl ions, N .

- D. " " " NaOH.
- E. N-Butyldiacetoneamine " KOH.
- F. " " " NaOH.

nitrosotriacetaminine which has been more closely examined than the others. It will be noticed that the curve for hydroxyl ion concentration from sodium hydroxide does not quite coincide with that from potassium hydroxide; probably this is due to neutral salt action. Velocity determinations of the decomposition of other nitrosoamines in concentrated hydroxyl ion solutions are shown in fig. 3.

The effect of neutral salts on the velocity constant of the decomposition of nitrosotriacetaminine when the concentrations of hydroxyl ions are small, is shown in fig. 4, where the percentage retardations are plotted against the concentration of the neutral salts used.

FIG. 4.

Concentration of salt, N .

Effect of Neutral Salts on Catalysis of Nitrosotriacetaminine. Conc. $\text{OH}^- = 0.0455\ N$, $t = 30^\circ$.

The group of curves in this case may be compared with a corresponding set for nitrosovinylidiacetaminine where the velocity determinations were made at 50°C . (fig. 5). Comparison shows the very

FIG. 5.

Concentration of salt, N .

Effect of Neutral Salts on Catalysis of Nitrosovinylidiacetaminine. Conc. $\text{OH}^- = 0.1602\ N$, $t = 60^\circ$.

striking similarity that exists between the two sets of observations, which, it will be noted, were carried out with different nitrosoamines and at different temperatures.

The effect of neutral salts on the velocity constant in high concentrations of hydroxyl ions is shown in fig. 6. As in the previous figures a dotted curve indicates that the constants are "drifting" and a mean value has been taken. It is possible that the addition of such salts as

potassium iodide and thiocyanate may depress the dissociation of the potassium hydroxide and hence accelerate the reaction to such an extent that the concentration of hydroxyl ions falls to that region

FIG. 6.

Concentration of salt, N .

Effect of Neutral Salts on Catalysis of Nitrosotriacetaminine. High Conc. of OH^- , $t = 30^\circ$.

which I have termed the "drift" region, and possibly beyond where the relationship between velocity constant and concentration of hydroxyl ions is expressed by a straight line.

It follows from this brief sketch of the effects of neutral salts, that when this method is employed for the determination of alkalinity in the presence of a large excess of such substances, a due allowance must be made in the value of the velocity constant which may be found, and the method may lose some of its convenience as a means of estimating the concentration of hydroxyl ions in such solutions. The following table gives the relationship between the hydroxyl ion concentration, and that of sodium hydroxide and potassium hydroxide at 30°C ; from $1\ N$ upwards the temperature is 40°C . At low concentrations the dissociation of potassium and sodium hydroxide is very similar.

Conc. of base N .	Conc. $\text{OH}^- N$ for KOH .	Conc. $\text{OH}^- N$ for NaOH .

DISCUSSION.

Dr. J. C. CALN said that the apparatus was very similar to one which he had used but which had been much criticised on account of the possibility of supersaturation of nitrogen in the liquid unless it was exceptionally well stirred by a mechanical agitator.

Dr. RIXON asked whether there was any difference in the constants obtained with the forms of apparatus described.

Dr. H. W. BYWATERS asked if the apparatus could be used to determine the hydroxyl ion concentration of blood or similar complex substances.

Prof. FRANCIS replied that the question of supersaturation depended upon efficient shaking. The whole of the apparatus was placed in a thermostat and shaken vigorously, and unless this shaking was vigorous, supersaturation would vitiate the

results. In reply to Dr. Rixon, he said the volume measurements in both cases were carried out under atmospheric pressure, so that the results were comparable. It was possible to measure extremely small concentrations of hydroxylic ions by his method, but it had never been used for physiological liquids.

THE APPLICATION OF THE CENTRIFUGE IN COMMON LABORATORY PRACTICE.

BY F. W. RIXON, PH.D., M.Sc.

An attempt has been made to construct and test a centrifuge that would be in price within the reach of the smallest laboratory, and at the same time allow an application of ordinary laboratory methods and quantities in its usage. Any motive power may be employed, the most satisfactory being a motor provided with a substantial starting resistance that will not burn out if the motor is run for some time at low speed. A small sixteenth-horse power motor has been used with success.

Hand or foot drive may be used. A convenient and readily procured gearing can be made by replacing by a pulley the emery wheel of a grinding machine, and lengthening the handle. The drive is carried by a round leather belt (sewing machine belting) to a stepped and grooved pulley mounted on the driving spindle of the centrifuge, which is of simple construction and can be built by any capable mechanic. The spindle is practically an elongated back wheel bicycle bearing, one ball bearing being sunk on a heavy iron base, the other mounted on a stout tube which surrounds the spindle for about

half its length and is then screwed into a stout cross-piece supported on two pillars which are bolted to the heavy iron base. Immediately below this cross-piece the stepped and grooved pulley is fixed on the spindle by a set screw. To the upper end of the spindle an arm is fixed by means of a nut; this arm carries in plain bearings at each end

a rod which screws at each end into collars on which are fixed thin brass tubes of such size that the usual 6 in. \times 1 in. test tube is a snug fit with about an inch projecting above the collar. A small pad of cotton wool is at the bottom of each tube. The full load of this model is therefore four such test tubes.

Modifications in design suggested by a lengthy use of the model are a tripod mounting for the top spindle in place of the present tube and cross bar, and in place of the arm, a disc with attachments for a greater number of tubes, variable at will.

The centrifuge should be firmly fixed to a stout bench and have some protective covering—a cage of stout galvanized wire netting with one side cut away slightly for the drive answers this purpose. The belt is always used crossed.

Ordinary test tubes, if selected carefully, serve most purposes; where comparatively high temperatures have to be used in operations subsequent to centrifuging quartz test tubes are substituted.

Further details can be seen on the figure, where the more essential dimensions are noted.

Such a machine as that described, with motor and resistance, represents an outlay of about £5; its value has been very evident during three years' use in the laboratory.

In preparative work the separation of substances difficult to filter is effected more rapidly than by suction filtration. Separation of crystals from solvent and subsequent washing can be rapidly and easily carried out. In almost all cases the solid settles in the tube in the form of a cake which is not disturbed when the liquid is poured off and yet is sufficiently soft to be broken up by vigorous shaking; this is the case not only with crystals but with precipitates also, and thus it is possible to abbreviate a qualitative analysis very considerably.

In gravimetric analysis the curtailing of the usual processes should be very marked. It should be possible in a great number of cases to carry out the whole of an estimation in one vessel, thus avoiding not only the errors of transference but also the use of filter paper and the after-treatment of the paper.

A number of test analyses which have been carried out have indicated the utility of the method. The procedure in general was as follows:—A glass or quartz tube was thoroughly steamed out, dried, and weighed. The temperature at which the tube is dried should approximate to the final temperature of the analysis. The substance to be analysed is weighed into the tube; the amount should be less than that taken for ordinary analysis, particularly if the precipitate to be formed is strongly adsorptive, such as barium sulphate or aluminium hydroxide, when the weight taken should be about one quarter the usual. In such cases also large excess of reagent should be avoided. The substance is dissolved, precipitated, and centrifuged (if only one tube is being dealt with it should be balanced in the machine by a dummy), and the clear liquid is poured off, the precipitate broken up and washed by shaking or boiling, again centrifuged, and the process repeated until the washings are satisfactory, then as much as possible of the final washing is poured away, and the precipitate dried by heating first in an oven and finally over a burner to the required temperature, cooled, and weighed; or the tube may be first cautiously heated over a small flame and when dry receive its final heating.

In certain cases a fine scum appears on the top of the liquid in the tube and refuses to sink, but it may be conserved in one of two ways. If the filtrate be poured into a similar tube and this tube filled to the top with water the scum may be blown back into the original tube by a smart puff, or the formation of a scum may be prevented by the addition of a very small quantity of a solution of saponin, a procedure recommended by Nolte, who carried out a series of determinations of potassium,

sodium, and calcium in a centrifugal machine of larger type (Landw. Versuchs-Stat., 1915, 449.) It may be mentioned that the cost of Nolte's installation was some £150.

The value of the method of which a general outline has been given may be seen from a few results obtained mainly by students, thus making the test a fair comparison.

In a series of precipitations of silver chloride from silver nitrate (each of which occupied $1\frac{1}{2}$ hrs.), the errors in weight obtained were -0.0007, -0.0006, -0.0009, -0.0005, -0.0006, -0.0006, and -0.0005 gm., the weight of precipitate being about 0.4 gm. Again, in precipitations of barium sulphate from barium nitrate the errors were +0.0001, -0.0015, -0.0023, -0.0010, -0.0006, -0.0007, and -0.0012 gm., the weights of precipitate varying from 0.2 to 0.75 gm.

A series of experiments in which barium sulphate was precipitated in presence of various salts gave interesting results, showing the method as lending itself to an examination of adsorption and emphasising the known adsorptive properties of this substance. In cases where a well-known adsorptive substance is present particular care should be taken to exercise restraint in the use of reagents and also of "original" material. If barium sulphate be precipitated by the addition of a large excess of potassium sulphate the results are uniformly high. Again, when barium sulphate is precipitated from magnesium sulphate by the addition of twice the theoretical amount of barium chloride, the errors are much higher in proportion when a larger weight of material is used. In dealing with small quantities it is advisable to weigh the tube used before and after the experiment as the weight loss during repeated boilings is with some types of glass quite appreciable.

A number of estimations of tin in solder were also made, the complete analysis being carried out in the tube. The percentage of tin found by the ordinary method was 24.50 (probably there is a constant method difference), the time taken for a single determination being three hours. The following results were obtained:—Sn 24.96, 24.92, 24.81, 24.89, 24.78, 24.87, 24.76%.

A number of other determinations have been carried out with equally satisfactory results. The method is one that offers in a great number of cases many advantages with a considerable saving of time and with little initial outlay, and it seems that almost all the approved gravimetric methods should be capable of suitable adaptation.

It is with pleasure that I thank the Colston Society for a grant towards the expenses of the work, also Mr. Alway, Mr. Tyler, and particularly Mr. Vincent for a large number of analyses carried out.

DISCUSSION.

Dr. H. W. BYWATERS said that a good deal of work had been carried out in America on the use of the centrifuge for the estimation of phos-

phates. He asked whether the results obtained in a centrifuge compared favourably with the ordinary gravimetric methods.

Mr. F. SOUTHERDEN asked whether the method was satisfactory in dealing with precipitates which did not settle satisfactorily, such as zinc sulphide. He suggested that where a large number of estimations had to be carried out, instead of weighing, the depth of the precipitate might be measured.

The PRESIDENT asked whether the author had used the method for such special work as the determination of phosphorus in iron and steel. There were several processes which measured the volume of the precipitate instead of weighing it for these determinations, and it appeared to him that the centrifuge ought to be specially applicable to these processes.

Dr. RIXON, in reply, said that he had satisfied himself that the machine could be used satisfactorily for a number of cases of gravimetric analysis. The application of the machine to methods in which the depth of the precipitate was obtained was quite possible, although he had not tested them. He saw no reason why the machine should not be used in practically any gravimetric analysis.

Dr. E. F. ARMSTRONG read a short paper entitled "Some Technical Applications of Catalysis," in which he dealt with recent developments in the catalytic synthesis of acetaldehyde and acetic acid. Under the present circumstances it is considered inadvisable to publish this paper.

On Wednesday evening the members were received at the Bristol Museum and Art Gallery by the Lord Mayor and Lady Mayoress, who were attended by the Sheriff.

The Annual Dinner was held at the Grand Hotel, Bristol, on Thursday evening, the President occupying the chair. Following the loyal toast, proposed by the President, the toast of the Society of Chemical Industry was proposed by Mr. Windus, and responded to by the President, and that of the Bristol and South Wales Section by Mr. Lloyd Howard, and responded to by Dr. T. H. Butler, who, in turn, proposed the toast of the University of Bristol, to which Prof. Francis replied.

The dinner was followed by an informal concert.

Friday afternoon was devoted to visits to the tobacco factory of Messrs. W. D. and H. O. Wills, Ltd., Messrs. Parker Brothers' tanneries, and the University Agricultural and Horticultural Station.

THE EXAMINATION OF COMMERCIAL DEXTRIN AND RELATED STARCH PRODUCTS.

BY F. W. BARRINGTON, ALFRED TINGLE, AND C. E. WATSON.

The materials to be considered come under two heads, *viz.*, (1) starches that have been so treated as partly to hydrolyse a portion of the material, and (2) mixtures of untreated starches with starch that has been submitted to hydrolysis. Both classes of material may be treated analytically in the same way.

Starch furnishes many and ill-defined products when hydrolysed, but for commercial purposes it often suffices to distinguish between, and determine, "starch" and "dextrin gum."

Our increasing but still incomplete knowledge of this branch of carbohydrate chemistry has caused the name starch to have a wider and more vague meaning than formerly, so that it is necessary to define the sense in which it is here used. Analytically we consider as starch the carbohydrate or group of carbohydrates which, whether soluble in cold water or not, form a solution or gelatinise with hot water, give a blue colour on treatment with iodine, and are precipitated by semi-saturation of the cold solution with barium hydroxide.

By dextrin gum is meant the mixture which results from the hydrolysis of starch when the change has not been carried so far as a complete conversion into sugars, though the latter may be present in the gum. "Dextrin gum" gives no blue colour with iodine and is soluble both in cold water and in a cold, half-saturated solution of barium hydroxide.

The method of Lamb and Harvey (J. Soc. Dyers and Col., 1918, 34, 10; this J., 1918, 133) for the analysis of these mixtures is not satisfactory. It includes as "starch" only insoluble starch, while soluble starch is determined as part of the "dextrin." We have found that when the starch and dextrin are mixed in certain proportions it is very difficult to wash the former free from the latter with water; filtration is very slow and the starch passes into solution during the process to a serious extent. With reference to our first objection, we admit that for many commercial purposes it may be desirable to determine soluble starch among the dextrins. To adopt such a practice in our own laboratory, however, would not be satisfactory, as importers would thereby be penalised.

A method of examination which is both short enough for practical purposes and scientifically accurate is much to be desired, but for the present we have aimed at simplicity of procedure and a probable error of less than 5%.

Determination of dextrin gum.—The sample (1 gm.) is warmed in a 100 c.c. graduated flask, with 30 c.c. of water until just gelatinised, and cooled quickly; 50 c.c. of a cold saturated barium hydroxide solution is next added (the flask being meanwhile shaken), followed by enough water to bring the total volume to 100 c.c. The solution is filtered through a dry 15 cm. paper and an aliquot portion (50 c.c.) of the filtrate is pipetted into a platinum dish. After the addition of 2 drops of a

1% phenolphthalein solution, *N/1* hydrochloric acid is added cautiously till the neutral point is just passed. A faint pink colour is then restored by the addition of two or three drops of the barium hydroxide solution. A weighed quantity (about 10 grms.) of sand is added, and the dish heated on a water-bath. The sand should be stirred when almost dry, to expose the maximum surface to the air, after which the dish is transferred to a well-regulated oven and dried to constant weight at 120° C., below which temperature crystallised barium chloride is dehydrated. Dextrin gum being hygroscopic, precautions must be taken accordingly. The dish is now heated strongly, but not beyond the temperature necessary for the complete combustion of the organic matter. During ignition the sand should be well stirred at intervals to allow full exposure to the air. The dish and contents are then cooled and weighed. The difference in weight before and after ignition represents the dextrin gum in 50 c.c. of filtrate, *i.e.*, in half the weight of sample taken.

Limit of accuracy.—The phenolphthalein and the barium hydroxide added in excess of neutrality are obvious sources of irregularity, but if the amounts laid down above are not exceeded this is unimportant. A blank determination showed that the total resultant error from this source was 11 milligrams or 0.22% on the basis of a 1-grm. sample.

The precipitation of starch by barium hydroxide is not quite complete, and that portion which remains in solution must ultimately be weighed as dextrin gum. The error likely to arise from this cause was found by making blank determinations of dextrin gum in two samples of starch. No. 1 was arrowroot and No. 2 a corn starch.

No.	Weight of sample.	Weight of dextrin gum found.	Dextrin gum found, %.
1	grms. 1.00	grms. 0.0053	% 1.06
2	1.00	0.0087	1.74

Varying weights of arrowroot starch were added to measured volumes of a well standardised dextrin solution and these mixtures were examined by this method, with results shown in the following table:—

Mixture No.	Weight of starch taken.	Weight of dextrin in solution.	Dextrin, %.	Total weight of dextrin gum found.	Dextrin gum found.
1	grms. 1.50	grms. 2.4879	% 62.3	grms. 2.4130	% 61.2
2	1.00	2.4879	71.3	2.3700	67.9
3	1.00	2.4879	71.3	2.5044	71.8
4	0.50	2.4879	83.2	2.4858	83.1

The error is thus within the limit aimed at, though much larger than would be tolerable for purposes of careful scientific enquiry.

Mixtures of unknown composition were next examined, all being ordinary articles of commerce. They were:—(A) "Yellow dextrin"; (B) "Soluble starch"; (C) "Soluble gum" (a textile dressing); (D) "Treated starch" (believed to be a starch which had been washed with dilute acid). Each sample was examined independently by two analysts, so that differences in the result of duplicate analyses display all the error which can arise from "personal equation." The results obtained were as follows:—Dextrin gum % in (A) 99.90, 99.74; (B) 11.60, 11.86; (C) 24.00, 25.00; (D) 17.00, 15.72.

If dextrin gum is determined by the above method and determinations are also made of ash and moisture, the starch may then be estimated by difference. Such a procedure is not always desirable, and we have commenced work on a method for estimating the total starch directly, by means of the polarimeter, after hydrolysis. The pressure of departmental routine has prevented the completion of our experiments. At present it is enough to say that we have found that starch which has been precipitated by barium hydroxide is somewhat more rapidly hydrolysed by hydrochloric acid than when not so treated. Whether the hydrolysis is complete we are not prepared to say, but we find that under our experimental conditions (100° C. at atmospheric pressure) no further reduction in rotatory power can be observed after 1½ hours. Pending the completion of this work we suggest that the following determinations on such starch products as we have been considering will meet most commercial requirements:—(a) Ash. (b) Moisture. (c) Dextrin gum by the method described here. (d) Insoluble starch and (e) reducing sugars by some such method as that described by Lamb and Harvey (*loc. cit.*). (f) Total starch by difference [100 - (a + b + c)]. (g) Soluble starch by difference [f - d]. (h) Non-reducing dextrin gum, by difference [e - c].

Our method may also be applied to mixtures of starch and gum arabic, such as are sometimes met with commercially.

THE UTILISATION OF THE PEAT RESOURCES OF CANADA.

BY B. F. HAANEL.

Canadian peat deposits.

The total area of Canada covered by peat bogs has been estimated to be 37,000 square miles, and the average depth of the peat deposits is put conservatively at 6 feet. A large portion of this area is in the North-west Territories, and the Yukon, and is not at present of economic importance, but over 12,000 square miles are situated in the central provinces of Canada.

Assuming that all the peat in this 12,000 square miles is suitable for the manufacture of fuel, it represents a quantity of standard peat fuel (containing 25% moisture) equivalent to over nine billion tons, which, on a basis of actual heating value, is equivalent to over five billion tons of good anthracite coal.

During the past ten years the Mines Branch, Department of Mines, has completely investigated and mapped 58 Canadian bogs, all of which are situated conveniently with respect to inhabited and industrial communities, railway and other transportation facilities. The investigations are conducted to determine the principal and controlling characteristics of a bog, *viz.*, its area, depth, quality at different depths, quantity in tons, and, in general, its suitability for any particular purpose. The area examined in detail comprises 170,000 acres, and represents a quantity of standard peat fuel estimated at 120,000,000 tons. Seven bogs

conveniently situated with respect to Toronto could supply that city with 26,500,000 tons of fuel, and seven bogs within easy reach of Montreal could supply 23,500,000 tons of fuel. Excellent bogs are, likewise, conveniently situated with respect to thickly inhabited communities in Nova Scotia, New Brunswick, and other parts of Canada.

Past efforts to create a peat industry.

Whether or not a particular natural substance shall be exploited, has usually been decided from a "profit" point of view. Peat, not holding forth great prospects for fabulous profits, failed to attract the attention of large capitalists and industrial men, and therefore the creation of a peat industry was left in the hands of a few earnest and honest men with insufficient capital to succeed in an undertaking of this kind, and a few dishonest promoters. Several attempts have been made and as many failures with loss of capital involved have been recorded. But the larger portion of the capital lost could have been saved and a flourishing peat industry long ago established if the promoters had been advised by accredited engineers who understood their business. Instead, however, of profiting by the experiences of European investigators, money was expended in developing and testing ideas which had long ago been discarded as impracticable and, in many cases, impossible in the peat-using countries of Europe. Not until the results of the investigations conducted by the Mines Branch of the Department of Mines concerning the economic methods employed for the manufacture of peat fuel in European countries were placed at the disposal of the public, were men with unpractical ideas dissuaded from interesting people in their schemes.

I believe that the time is at hand when necessity will decide that Canadians utilise their peat resources, and in the most efficient manner. The exploitation of natural resources, by the individual, for the sole purpose of creating huge profits appears to be a thing of the past—at least it is to be hoped so.

Description of peat.

Peat is a substance formed by the incomplete decomposition of vegetable matter either in, or in the presence of, water. The deposition of peat-forming matter may not be continuous, but may occur at irregular intervals; moreover, the vegetable matter composing the *detritus* laid down in the different periods may be of many different species. Consequently, a bog of considerable depth will have represented in it a series of strata or layers which may comprise many different forms of plant life. The stages of decomposition to which the various layers have proceeded may also be quite different. Material composing a peat bog may consequently be far from homogeneous.

The layers composing an old and well-humified peat bog are often so altered that scarcely a trace of the original plant structure remains. In such cases the peat mass is composed of such minute particles that in its natural state (associated with water) it possesses many of the properties of a colloid. The chemical alteration of the plant substances entering into the formation of all peat bogs gives rise to hydrocellulose, a gelatinous substance possessing the property of absorbing many times its own volume of water. It is a true colloid, and has properties which are of the greatest importance in the manufacture of peat fuel. This substance is distributed throughout the peat bog, but the quantity present in any particular section or layer is dependent on the nature of the plants composing such portions or sections and the degree to which the humification, or chemical alteration, has proceeded. It is, therefore, seldom, if ever,

found uniformly distributed throughout an entire bog.

Peat, in its natural state, is generally associated with about nine times its weight of water, and, moreover, the solid matter represents not only combustible substance, but also ash and other mineral matter. The separation of this large quantity of water, and the handling of so large a quantity of raw peat substance, in order to obtain a comparatively small quantity of combustible matter, represent the real problems in converting peat into fuel, on a commercial basis, and in a thoroughly economic manner.

Ignorance of the physical and chemical properties of peat, and a complete lack of knowledge concerning the results of the efforts made by European investigators, distributed over more than a century, are directly responsible for the lamentable failures with which the attempts in Canada have met.

Manufacture of peat fuel.

In order to remove the water content of peat, and to convert the substance into a convenient form of fuel, many people have proposed to employ presses of various designs, and to briquette the residue. All such attempts were doomed to failure, since the very nature of peat prohibits the employment of pressure for the removal of the water. The water content of well-humified peat cannot be reduced to below 80–85% by pressure alone, and, even in the case of very fibrous peats, it has been only possible to reduce the water content to a trifle below 80% by pressure. The bulk of the water content, therefore, must be removed by other means, that employed usually having been artificial heat. Such processes, employing pressure and artificial heat, are absolutely uneconomical, and, under present conditions, any process devised for the manufacture of peat fuel which depends on the employment of pressure or artificial heat, or both, for the removal of the water content, will inevitably result in failure.

M. Ekenberg, a Swedish chemist, who devoted a large part of his life to the investigation of problems connected with the manufacture of peat fuel, considered that the great difficulty with which peat parted with its water content was due to the hydrocellulose. He, therefore, attempted so to alter this substance chemically that the residue resulting would more readily part with its water by pressure alone, and he devised a process according to which the raw peat, containing upwards of 90% of water, was submitted to high temperature and pressure in specially designed iron tubes. The material was carbonised, the hydrocellulose was decomposed, and a material, considerably richer in carbon and of an appreciably higher calorific energy, was produced. But this altered substance still refused to part with the major portion of its moisture through pressure. The bulk of the water still had to be removed by artificial heat. Although several million dollars have been expended on this process by an English syndicate, and about forty thousand dollars more by the Swedish Government, it is to-day not a commercial success.

Peat fuel, however, is being manufactured economically and on a commercial scale in many of the European countries, and this industry has been expanding and growing more secure.

The only economic process in existence to-day is that which employs the sun and the wind for removing the moisture. This process is called the "wet process," and the product obtained is termed "machine peat." This is the process which the Mines Branch, Department of Mines, demonstrated at the Government peat plant at Alfred, Ont.

The "wet process" consists of the following steps:—(1) Excavating the raw peat by hand or

by specially designed mechanical excavators. (2) Transferring the excavated material to the hopper of a specially designed macerator. (3) Transferring and spreading this pulped peat on the portion of the bog prepared for drying purposes. (4) Cutting the spread peat, when sufficiently set, transversely and longitudinally into blocks, which, when dried to about 35% moisture, have the dimensions of ordinary building bricks.

The macerator, which performs, perhaps, the most important function of the entire process, consists of a cylindrical shell, inside which is a set of spiral rotating knives and a set of knives fixed to the inside of the cylinder. The material fed to the hopper is forced by the spiral knives through and against the fixed knives. The fibres, stems, and pieces of wood, which are often found scattered throughout a bog, are cut, torn or ground into small fragments, and the peat composing the different layers of the bog and the hydrocellulose are thoroughly intermixed. The degree to which pulping is carried is determined by regulating the opening of the spout through which the pulped material has to pass.

During the drying stage, the hydrocellulose content of the peat performs a very important function. It serves to bind the particles of the peat together, forming a concrete whole, and prevents the peat blocks from re-absorbing moisture when the drying period is interrupted by wet weather. This waterproofing of the peat block is due to the fact that the colloidal substance forms a skin covering the outside of the block, which always assumes a state of complete saturation. Hence it acts as a vehicle for conveying the moisture from the inside of the brick to the atmosphere. The moisture evaporated from the outside of the block by the sun's heat is immediately balanced by moisture drawn from within. This equilibrium is always maintained until drying is complete. During rainy weather the rain brings the skin to its maximum saturation, thus preventing moisture from reaching the interior of the block. The blocks, as the drying proceeds, contract and become denser and more resistant to breakage.

The Department of Mines manufactured, during the two seasons the Government plant was in operation, about 3000 tons of standard peat fuel. A large part of this was sold at a nominal price to householders in Ottawa and in the vicinity of the plant; 150 favourable opinions regarding the value of this fuel, from those who tried it, were collected by the Canadian Peat Society, and published in their Journal.

Cost of manufacture.

The results of the manufacturing operations conducted at Alfred indicate that, with strict business management, peat can be manufactured for \$1.70 per ton on the field. This figure includes all overhead charges, such as interest on investment, amortisation, etc. The machine employed depended on hand-dug peat, and, for an output of 30 tons per day, 14 men were required.

The newer plant which was erected on the Government bog, after its sale to private parties, was equipped with mechanical excavators, spreader, cable-way for transporting pulped peat to drying field, and many other innovations and improvements. Mr. E. V. Moore, who erected this plant, and operated it during the experimental stage, informed the author that the results obtained showed that peat could be manufactured at a cost considerably below that obtained with the Government plant. The conditions prevailing at the time war was declared unfortunately prevented the operation of this plant under thoroughly commercial conditions.

Properties of peat fuel.

The following is a summary of the properties of peat manufactured as described:—

* "Peat is a clean fuel to handle; has, as a rule, a very low ash content, and produces no soot or other deposit when burned in an ordinary cooking stove or open fireplace. The ash, moreover, is in a very finely divided condition, free from combustible matter, and can be easily removed from the stove or fireplace. Clinkers are not formed. On account of the ready manner in which peat fuel ignites, often a little paper or a few shavings are sufficient to start the fire. Peat fuel, on the other hand, is more bulky than coal and is of lower heating value per pound. The relation between anthracite coal and peat fuel as regards heating value per pound is 12,500: 7000 or 1.8: 1, that is, one pound of the average anthracite coal is equivalent in heating value to 1.8 pounds of peat fuel, containing 25% moisture. For a definite heating value, therefore, it is necessary to store 1.8 times the weight of the coal required in peat fuel. The volume occupied by the peat fuel, owing to its low specific gravity, will also be much larger than that of coal. One cubic foot of ordinary furnace anthracite coal weighs approximately 56 pounds, while one cubic foot of machine peat weighs about 27 pounds. The volume of peat required to equal coal of the above heating value will, therefore, be about 3.6 to 4 times that of the coal."

Peat is an excellent fuel for many of the domestic purposes for which coal is commonly used, and can, if certain changes are made in the design of house heating plants, be utilised in general for house heating. But peat possesses certain chemical characteristics which make it specially valuable as a source of nitrogen.

Nitrogen content of peat.

The peat bogs so far examined in Canada all exhibit a high nitrogen content, and certain of them have an unusually high nitrogen content. Peat, therefore, becomes a most valuable source of nitrogen for the manufacture of ammonia and other nitrogen compounds.

In thirteen of the bogs so far examined in the province of Ontario, the nitrogen content of the peat reduced to a basis of 25% moisture is 1.3%. The total standard fuel content of these 13 bogs is 43,000,000 tons. The total nitrogen available is, consequently, 560,000 tons, and this quantity will give, with present day efficiency of recovery (as obtains with the by-product recovery producer) 1,800,000 tons of ammonium sulphate. This, of course, is simply one of the by-products. I shall refer to the process employed later.

Utilisation of peat fuel for industrial purposes.

For power and metallurgical purposes it has been demonstrated that peat is an efficient and entirely satisfactory substitute for coal. Coal, of course, is much more convenient to handle, but the requirements of the one can be fulfilled by the other, provided the cost is the same.

The problems presented in the utilisation of peat fuel for the generation of a power gas, with or without by-product recovery, have been solved with entire satisfaction, and the use of peat for the generation of steam for power or other purposes is an assured economic fact. So far as the use of peat for metallurgical purposes is concerned, we can point to the by-product recovery peat coking plants in Germany and Russia.

It will be seen, therefore, that peat has been and can be used for very nearly all of the purposes for

which coal for over a century has been the only fuel used. But for certain reasons the plants erected at large expenditure to accomplish these ends are no longer in operation, although the products obtained have been eminently satisfactory. In regard to the large peat coke plants operated for some time in Germany, and which, for several years, have been closed down, the companies' statements show that the businesses were profitable, and the products met with a ready sale and at fairly high prices.

The entire trouble is to be found in the difficulty of supplying the requisite quantity of sufficiently dry peat to permit the plant to operate at full capacity throughout the year, and to supply a product (coke in this instance) which could be sold sufficiently cheaply on the open market to compete with coal coke. This is the great trouble with many of the larger undertakings of a more or less complex nature: the factors involved are not known, or else are not well enough understood, and, since the demand for the special products under consideration can or could be met by the products obtained from coal, the necessity for manufacturing the former product was not apparent. As coal becomes scarcer, and its price per ton rapidly increases, so will that of all the products derived from it, and then the above described peat-coke plants will come into their own. This time is not far off.

The treatment of peat fuel in gas producers, with or without by-product recovery, presents, however, a totally different aspect. In the case of a gas producer without by-product recovery, that fuel is used which experience shows is the cheapest, and the problem is simply one concerning the relative cost of peat fuel and other fuels obtainable.

In the case of by-product recovery plants, the situation is somewhat different. It is presumed that the principal aim of all by-product recovery producer-gas plants is the generation of a power or industrial gas with the maximum recovery of ammonia. Consequently, the nitrogen content of the fuel becomes one of the governing factors—in certain cases the governing factor.

This is a case where peat might successfully compete with coal, even though for a definite heating value peat be more expensive than coal. The profits resulting from the recovery of sulphate of ammonia increase rapidly with an increase in the nitrogen content of the fuel. It will at once be evident why certain of our peat bogs, in which the nitrogen content is over 2%, are so valuable for this kind of exploitation.

Plants of this description have been erected in Italy and Germany, for the purpose of generating electricity and recovering the nitrogen of the fuel as ammonia. One plant, in fact, near Venice, Italy, was established for the sole purpose of recovering the nitrogen content of the peat fuel. Two Italian plants are in operation to-day, even though at one of the plants the peat is of inferior quality as regards both its calorific energy and nitrogen content, and is exceedingly difficult to win.

The German plant, according to last reports, is out of commission, owing to the fact that the nitrogen content of the peat proved to be too low for profitable operation. Trouble was also experienced in the winning of the fuel. The tars obtained as a by-product at these plants were not considered to be of sufficient value for special treatment, so were burned under the boilers to help conserve fuel.

There are several bogs situated near certain of our industrial centres which are exceptionally high in nitrogen, of excellent heating value, and thoroughly satisfactory as regards quantity of fuel. If these bogs were exploited in the manner above outlined, and developed on a sound business basis, failure would be impossible. In fact, it has been

* From address given by Dr. Eugene Haanel before Conservation Commission, Ottawa, November 27, 1917.

shown that, in special cases, a large profit on the investment could be made on the recovery and sale of the sulphate of ammonia alone, *i.e.*, assuming the power gas to be thrown away. Such installations do not, however, prove profitable when under a certain capacity, *e.g.*, 4000 horse power is the least capacity recommended.

Generation of a power and industrial gas.

The comparatively low heating value of peat fuel, together with its high water content, make it imperative that this class of fuel be utilised as close as possible to the source of its manufacture. Only when long hauls are obliterated and every possible economy is introduced in the manufacture and utilisation of the fuel, can peat for general purposes be employed in competition with coal. Since peat, as a rule, is so rich in nitrogen, every effort should be made so to utilise it that the highest possible recovery of the nitrogen could be realised. The profits derived from the by-products would appreciably decrease the cost of the power or power gas, if this were the principal object. A plant suitably situated with respect to a city or group of towns or villages could supply a gas which could be used for power, industrial, or domestic purposes, thus rendering those communities entirely independent of coal for heat for all purposes. The gas for various purposes could be transmitted through special mains to the towns or cities, and then supplied through the gas mains already in place, providing such arrangement could be made.

A large manufacturing and industrial area in South Staffordshire, England, is supplied with a power and industrial gas generated at a large Mond gas plant situated near a source of low grade coal. There is no reason why similar plants using peat should not be erected in this country, especially in those portions which are dependent on imported coal for heat (both industrial and domestic).

In regard to the utilisation of peat fuel for the generation of steam power, I shall only make the general statement that there are conditions and situations in this country which would be entirely favourable to the use of peat for this purpose.

Peat as a source of oil and retort gas.

The rapidly increasing demand for oils suitable for use in internal combustion engines, and the known scarcity of petroleum products in Canada, naturally prompt us to consider our own available sources of oils.

The principal source of oil other than the petroleum fields of Ontario exists in our oil shale deposits of New Brunswick, and, perhaps, those existing in other provinces of Canada. Certain of the lignites of the western provinces should in time become a valuable source of oils, and, to a certain extent, peat could be utilised for this purpose.

In the manufacture of peat coke, as conducted in Germany prior to the war, the following by-products were obtained from the distillation of the tar recovered:—Light oils, for either illuminating purposes or the manufacture of oil gas. Heavy oils, suitable for lubricating purposes. Paraffin, phenol, and asphalt. Tar water, containing ammonia, acetic acid, and methyl alcohol. When coked according to the Zeigler process 516 tons of peat containing C 35.3, H 3.4, N 0.7, S 0.1, O 28.4, ash 0.9, moisture 31.0%, and having a calorific value of 3792–3423 calories per kilo., or 7825–6161 B.Th.U. per lb., yielded 163.7 tons of peat coke, 25.8 tons of tar, and 269.0 tons of tar water. The 25.8 tons of tar yielded on distillation 11.6 tons of light oils, 3.9 tons of heavy oils, 1.8 tons of paraffin, 7.6 tons of phenol, and 0.8 ton of asphalt, a total of 4.5% of the weight of peat coked. The 269.0 tons of tar water yielded on further treatment 1.8 tons of methyl alcohol,

0.9 ton of ammonia, and 2.5 tons of acetic acid. The heating value of the gas produced was 322 B.Th.U. per cubic foot.

The above figures are taken from the Mines Branch Report: "Peat and Lignite: their Manufacture and Uses in Europe."

Attempts have also been made to retort peat for the sole purpose of generating illuminating gas, but they failed owing to the high cost of the peat used.

The utilisation of peat for the production of coke, illuminating gas, or for the recovery of oils alone, depends entirely on the quantity of peat fuel available, and the price at which it can be obtained. It is not a difficult matter, therefore, to decide whether or not the utilisation of peat for such purposes is feasible.

The establishment of a peat industry.

Many attempts have been made to start a peat industry in Canada, but for various reasons they have all resulted in failure. A flourishing peat industry must be established, despite past failures but we cannot afford to have any more such attempts terminate in this way.

The establishment of a peat industry along the lines suggested demands the support and sympathy of the various recognised engineering professions. In the first place, no attempt should be made to manufacture peat fuel without the aid of a well recognised peat engineer—one who is thoroughly familiar with the laying out of a bog for manufacturing purposes, and competent to design, erect, and operate the machinery required; and, secondly, no new processes or revolutionary improvements on well-known economic existing processes should be considered until the manufacture of peat fuel on a commercial scale according to a well-known and well-tried economic process has been securely established. Then, and only then, can attention be directed towards the improvement of existing processes, or the devising of new ones.

The erection of chemical, metallurgical, or power plants designed for the exclusive use of peat fuel, should never be attempted until specialists in the various lines involved are consulted, and the entire proposition considered from every possible angle. If such care is taken, failure will not result, and the erection of one successful plant will lead to the rapid erection of others.

Finally, the people of Canada should be educated to realise the necessity of utilising their own resources, even at some sacrifice in the beginning, instead of those obtained from some foreign source. In fact, this idea appears so important that I would even advocate Government legislation which would assist in, and insist upon, the utilisation of our own natural resources.

APPLICATION OF THE POLENSKE METHOD TO THE ANALYSIS OF SOAPS AND FATTY ACIDS.

BY PERCIVAL J. FRYER, F.I.C.

No mention has apparently been made of the use of the Polenske method (measure of the insoluble volatile fatty acids) in the analysis of the insoluble mixed fatty acids from oils and fats. In the examination of soaps, as well as of commercial fatty acid mixtures, the original oils are not available; yet, in the former case especially, coconut and palm kernel oils have been very largely employed for the special properties which they confer on the soap.

The author has investigated the subject, and finds that, although the usual saponification is unnecessary (the volatile fatty acids distilling over on simply boiling with water), it is advisable to adopt the standard method, especially in view of the fact that the fatty acids from commercial soaps as well as industrial samples of fatty acids frequently contain proportions of neutral oils and fats.

In all cases examined of soaps made from coconut and palm kernel oils, the liberated fatty acids gave, on distillation, considerable proportions of soluble volatile acids, amounting to one-half to nine-tenths the normal Reichert-Meissl values. The figure was variable, according to the amount of water used to dissolve the soap and whether the fatty acids were subsequently washed.

It was found convenient to use the standard weight of material, *i.e.*, 5 grms., for the estimation, all the other details of the standard method being observed. (The weight of sodium hydroxide employed, *viz.*, 1 gm., was sufficient to neutralise the fatty acids and leave sufficient excess to ensure saponification of any neutral glycerides present.)

In the case of soap it is desirable—though not absolutely essential—that a uniform method of determining the fatty acids should be employed. The following is suggested: The percentage of fatty acids in the sample is ascertained, and a quantity of the soap taken equivalent to 10 grms. of the fatty acids (thus in case of a 60% soda soap 16.6 grms. is used; or with a 40% potash soap 25 grms.). Water is added to make the weight up to 200 grms., the mixture heated to complete solution, a few drops of methyl orange added, and then sufficient dilute (1 in 4) sulphuric acid to give a decided pink coloration. The solution is warmed till the fatty acids melt completely and

the aqueous liquid is quite clear, transferred to a separating funnel, the aqueous layer run off, the fatty acids shaken with four successive quantities of 100 c.c. of boiling water, and the clear acids filtered through a thick dry filter paper.

The standard Polenske method is carried out as follows: 5 grms. of the fatty acids is weighed into the standard (300 c.c.) flask, 2 c.c. of 50% caustic soda added, and the flask heated, with constant agitation, till the liquid suddenly clarifies. It is allowed to cool to about 100°, and 100 c.c. of boiling water is added and the soap dissolved. After addition of 0.1 gm. of powdered pumice the soap is decomposed with 40 c.c. of 6% sulphuric acid, and the flask connected with the standard condenser, heated gently till the fatty acids are completely melted, and 110 c.c. distilled in 19–21 minutes. The distillate is placed in water at 15° for 15 minutes, and is then filtered through a wet filter paper. The condenser and receiver are washed through with 18 c.c. of cold water, which is used to wash the fatty acids on the filter, and the condenser is then cleansed with four washings of 10 c.c. of neutral alcohol, which are run into receiver and poured over the filter and collected in a titrating flask, the mixed alcohol solutions being then titrated with N/10 alkali. A blank test is unnecessary, provided the alcohol used is carefully neutralised.

The author obtained the following average figures for the "insoluble" volatile fatty acids of coconut and palm kernel oils: Coconut 17.3%, palm kernel 10.5%.

The method of Burnett and Revis (Analyst, 1913, 38, 255; this J., 1913, 704) is also equally applicable for the discrimination of coconut and palm kernel fatty acids in mixtures of these with other acids. In this case N/10 baryta is used for the titration.

THEORY OF THE COAGULATION OF HEVEA LATEX.

In a paper bearing the above title, by M. Barrow-cliff, published in this Journal, February 15, 1918, p. 48 T, credit was given to Whitby for the first suggestion (in 1912) that natural coagulation of latex is brought about by an enzyme. Mr. Barrow-cliff now writes that his attention has been drawn to the fact that the same suggestion had previously been made in 1908 by Dr. Spence, who, in a communication read before the Rubber Congress in London, entitled "The Practical Significance of Recent Advances in the Bio-chemistry of the Latex of Rubber-Producing Plants," stated that "the spontaneous coagulation of most latices and the acidity which gradually develops in fresh latex on standing are produced, therefore, largely by the enzymes present in the latex."

MR. T. H. WARBLEWORTH IN THE CHAIR.

THE DETERMINATION OF MOISTURE IN WHEAT.

BY DR. F. T. BIRCHARD.

There is at present no standard method for the determination of moisture in wheat, and as a result considerable confusion exists. Our investigations prove conclusively that the ordinary methods described in the literature and generally adopted and practised are not adequate. This difficulty has been recognised by a number of workers. Thus Barnes and Grove* invariably report the moisture in wheat under two headings, *viz.*, that which is obtained by heating to 70° C., and that which is found by heating to 100° C. Leavitt, while noting that a variation of 1° C. makes a marked difference in the moisture results obtained on wheat, claims that all the moisture could be driven out by heating to 100° C. for 4½–5 hours in an open-air oven. He states that if the heating is prolonged beyond this time an increase in weight occurs, but our experiments show conclusively that the increase is apparent only, since if a sample is put back into the oven for a sufficient length of time and re-heated at the same temperature a further decrease is noted. Swanson† also finds that if the ground grains are used, seven hours' heating in a water oven is sufficient, and that 40 hours is required in the case of whole grains. This also is not in accordance with our results, since again we found that if the sample is heated for a further period and re-weighed an additional decrease in weight is obtained.

Budai‡ believed that constant weight could be obtained by heating in an open oven to 170° C. for about three-quarters of an hour, and that the loss obtained represented the true moisture content. Duvel§ also states that the true amount of moisture can be obtained by heating the whole grains to constant weight at 107° C.

Without referring further to the literature, it may be stated that we have not been able to find any completely satisfactory method for this operation, the difficulty being that the loss in weight on drying depends chiefly on the temperature employed, but also on the length of time the grain is heated. Thus, for example, when wheat is heated in an ordinary drying oven or in a vacuum chamber continuously for many months, we have been unable to determine the point at which no further loss in weight takes place. It is true that after a certain time the losses are very small, but when the time of heating is prolonged the total effect is considerable. Also by raising the temperature slightly more loss occurs, and although we have employed a large range of temperatures, no definite end point could be found, as reported by other observers. Occasionally we also noted a slight increase in weight, providing the heating was of too short duration, but if prolonged further an additional decrease in weight is always to be noted, so that it is probable that while the figure obtained by heating until a slight increase in weight is noted, approximates to the true value, this cannot be regarded as the absolute amount of moisture present, since further heating in our

experiments gave off more than an additional 1% when the heating was prolonged for a sufficient length of time. Some of the details of these experiments will be referred to later.

The method commonly employed in commercial practice is known as the Brown-Duvel method, and consists in heating 100 grams of wheat in a flask of oil to 180° C., measuring the volume of water distilled over in a graduated tube, and regarding this as the true amount of moisture in grain.

Although no account appears to have been published describing the manner of standardising the Brown-Duvel method, I was personally informed by Dr. Duvel that the wheat was simply heated in a water oven to constant weight, and then the arbitrary conditions necessary for obtaining the equivalent amount of water with the apparatus worked out. But since it is not possible to heat wheat at any temperature to constant weight, the Brown-Duvel apparatus cannot be regarded as giving absolute results. Since, however, we have shown that this apparatus can give comparable results which are sufficiently accurate for all commercial purposes, and since also this method has been officially adopted by the United States Department of Agriculture and is very largely in use both in the United States and in Canada, it would seem advisable that this method should be officially adopted in Canada.

It will only be necessary to consider here a few of the actual experimental results obtained.

Table I. shows the impossibility of obtaining constant weight by heating crushed wheat in the vacuum oven for 40 hours, as reported in the literature. Table II. illustrates the same results using whole grains instead of crushed wheat, the experiment being conducted for 60 days. Table III. shows the effect of heating whole grains of wheat in the Abderhalden apparatus at various temperatures, and emphasises the importance of these factors and the impossibility of obtaining constant weight no matter how long the heating be continued. Table IV. shows the impossibility of drying whole wheat grains to constant weight in the electric air oven at a temperature of 104° or at 109° C. Table V. shows the effect of heating flour and starch in a vacuum as compared with whole grains of wheat.

A number of samples of ground wheat were dried in a vacuum oven (26 in. vacuum). The first series of experiments was conducted at a temperature of 98° C., and it was found that the samples were still losing weight when the experiment was discontinued at the end of 49 hours. In the second series at 99.7°, samples were also losing weight when the experiment was discontinued at the end of 74 hours.

These results show that for flour and starch constant weight can be obtained for each temperature, and that while increasing temperature gives rise to slight decrease in weight, this decrease is exceedingly small and the weight may be considered as practically constant.

The following experiments were conducted in order to determine the degree of accuracy on the Brown-Duvel apparatus: 1000 grms. of wheat, which by the Duvel machine showed a moisture content of 16.6%, was dried in stages at a comparatively low temperature (about 80° C.) in the Freas electric oven. At the end of each period in the oven it was cooled in the desiccator, weighed, and a Duvel test applied to the dried wheat. This was continued until the wheat was quite dry. In the first series of tests the loss on drying at 80° was 45.5 grms., while the loss indicated by the Brown-Duvel method was 47.7 grms. In the next case a difference of 1.1 gm. of water was found between the methods; in the third a difference of 1 gm.; in the fourth a difference of 0.1 gm. In the second series of tests (where 500 grms. of wheat only was employed) the differences were smaller, namely, 0.02, 0.03, 0.05, and 0.03 gm. These differences when calculated as percentages of the moisture in the wheat are exceedingly small; thus in the case of the greatest difference found this would represent only 0.3 c.c. on a sample of wheat of normal moisture content (13%), and if the average of the results were taken a difference of only 0.03 c.c., quite a negligible quantity. It is also shown that the Brown-Duvel apparatus is equally accurate whether it be dealing with wheat of high moisture or with wheat of low moisture content.

In a third experiment a large sample of dry wheat was well mixed. From the sample two lots of 80 grms. were weighed quickly and each placed in a Duvel distillation flask. To each of these 80 gm. lots 20 c.c. of water was added from a burette and the flask sealed up, shaken from time to time, and allowed to stand for about 20 hours. The flasks were then unsealed, 150 c.c. of oil added to each, and a Duvel test made on each in the usual manner. The moisture on dry wheat according to Brown-Duvel was 1.9%, corresponding to 1.5 c.c. in the 80-grm. sample, or a total of 21.5 c.c. in the sample tested. The amounts actually obtained in duplicate experiments were 21.6 c.c. and 21.7 c.c. In a similar manner 85 grms. of wheat was employed with the addition of 15 c.c. of water. In the first case a total of 16.6 c.c. of water should be present according to the Brown-Duvel test, while 16.8 c.c. and 16.7 c.c. were obtained in duplicate experiments. These results would appear to indicate clearly that the Brown-Duvel apparatus applies equally to wheat of low or high moisture content, and that reliable comparative results may be obtained therewith.

For the convenience of those not wishing to use the Brown-Duvel apparatus, we have determined a

series of temperatures and the corresponding length of time which must be employed to give results identical with those obtained with the Brown-Duvel apparatus.

TABLE VI.

	105	41
	110	28
	115	20½
	120	18
	125	10½
	130	8
	160	1½
Water oven ...	97	93
Abderhalden apparatus, vacuum 29 in....	99	52

All these experiments were repeated on wheats showing different characteristics, such as plump and thin grains, high and low moisture content, and in every case the results were the same. All the experiments, however, were confined to hard spring wheat, and whether any alteration would be necessary in the case of other varieties has not yet been determined.

Considerable variations occur in the temperature of the Freas electric oven at different points. This has also been observed by other workers. Thus not only do the different shelves show variations of several degrees, but different portions of the same shelf also show considerable differences. In the experiment described the samples were all grouped closely round the thermometers, and in addition a second thermometer was placed close to the sample on the shelf.

During the very prolonged heating of the wheat a gradual darkening in colour took place, which very slowly increased with the time of heating. At no point, however, can it be determined just where this discoloration first occurs; it is so very slight and so very gradual, some grains appearing to be more susceptible than others. A certain amount of chemical decomposition does occur even at the temperature of the water oven (approximately 98°), but as to the exact nature and extent of these changes little can be said at the present time.

In connection with the great difficulty experienced in drying wheat to constant weight, the remarks of Ostwald in "Foundations of Physical Chemistry" are not without interest. Speaking of colloidal precipitates, he says: "We have to remember that the vapour pressure of the exceedingly thin films of the moistening liquid is much less than that of the same liquid in the free state. The drying temperature must therefore be raised far beyond the boiling point of the liquid in order to get rid of the last traces of the latter, and the finer the powder the higher the temperature must be. Colloidal substances require the highest temperatures."

Summary.

It is not possible to determine the amount of moisture in grain by simply drying in an open oven or vacuum chamber at a definite temperature to constant weight or until an increase in weight takes place. A definite loss of weight occurs corresponding to the temperature employed and the length of time of heating, and increasing either of these factors leads to a still further loss of weight of the sample. Increase of temperature gives rise to an increased loss in weight that cannot be obtained at any lower temperature, no matter how long the heating be continued.

It is proposed that the Brown-Duvel method be adopted as the official method in commercial practice as the standard, and for those not employing this

apparatus other standard methods are proposed which give identical results. When the Brown-Duvel method is properly operated, the variation does not amount to more than 0.2%, and if the average of a number of determinations be taken, not more than 0.1%. For practical purposes this amount is negligible. Determinations made with other apparatus on the market, similar in principle, but not identical with the Brown-Duvel, give very different results, and experience shows that these are not reliable and bear no definite relation to those obtained with the Brown-Duvel apparatus.

Meeting held at Burlington House on June 3rd, 1918.

DR. CHARLES A KEANE IN THE CHAIR.

THE ESTIMATION OF PHENOL IN CRESYLIC ACID.

BY J. J. FOX, D.SC., F.I.C., AND M. F. BARKER, B.SC., A.I.C.

A short time ago we published an account of a method for the determination of phenol in commercial cresylic acid (this J., 1917, 842) which had for its object the determination of the proportion of phenol left after stripping out the main quantity. For many purposes, however, it is sufficient to ascertain whether the cresylic acid contains more than a small amount of residual phenol, say 5%. While our process is comparatively short, it is perhaps not rapid enough to serve as a method of estimation for the class of cresylic acid referred to. We have therefore devised the short method described below.

We take this opportunity of making a few additions to the description of our original method (*loc. cit.*) in order to clear up one or two difficulties which may be found in practice. In the process as described it has not been made quite clear that a sufficient quantity of ether must be used to dissolve all the tar acids and so facilitate the subsequent washing with sodium sulphate solution. Moreover, benzene may be used in place of ether for getting rid of bases and tar oils, and this will no doubt be found more convenient in works; in addition to this it is rather easier to operate with benzene than with ether when strong soda is used to dissolve the cresylic acid. It should be noted, however, that benzene is obstinately retained by the solution of tar acids in 20% sodium hydroxide and therefore the soda solution must be heated sufficiently strongly to expel all the benzene before acidification. Three treatments with benzene are required to remove neutral oils and tar bases, the quantity of benzene used depending upon the degree of impurity of the cresylic acid. After acidifying the soda solution to liberate the tar acids, the aqueous layer may be extracted with benzene instead of with ether, using three portions of benzene of 30–50 c.c. each. The whole of the tar acids are dissolved in benzene, to which the benzene extract of the aqueous acid layer is added. The washing with sodium sulphate solution and drying with calcium chloride are carried out as described (*loc. cit.*). When benzene is employed in place of ether it is necessary to heat the tar acids to 140° C., or even higher, before all the benzene can be considered to be removed.

The neutral oils and bases can also be conveniently removed by treating the cresylic acid with a

good excess of 20% sodium hydroxide—3 volumes at least—and distilling with steam until no more oil passes over with the distillate. If more dilute soda (10%) is employed, a greater excess is desirable in order to prevent tar acids (notably *o*-cresol) being carried over with the steam.

It is to be noted that when phenols are dissolved in the theoretical quantity of sodium hydroxide and subjected to distillation with steam, some of the phenol is carried over with the steam, the amount depending upon the dilution of the soda and on the acidic strength of the particular phenol under consideration. Hence, it is necessary to dissolve the tar acids in a good excess of soda to press back the hydrolytic dissociation.

In the examination for phenol of disinfecting fluids of the so-called saponified cresol type, which contain resin or other soap, tar acids, and tar oils, the extraction of tar oils by benzene or ether is usually impracticable because the fluid frequently dissolves completely in the benzene or ether. Steam distillation is also out of the question because of the frothing. The procedure adopted by us is to take 200 to 400 c.c. of the disinfecting fluid, acidify it with sulphuric acid (1 in 1 or 1 in 2), and collect the mixture of fatty acid, resin, tar acid, and tar oil. Only traces of phenol are left in the acid layer if tar oils are present in appreciable quantity, as is generally the case with disinfecting fluids except those of the "lysol" type. The mixture of fatty and tar acids, etc., is transferred to a Würtz distilling flask and distilled up to 220° C., when all the phenol and most of the cresols distil over, together with some or all of the tar oils. It is very rarely that decomposition or volatilisation of fatty acids occurs at this temperature. The mixture of tar acids and oils is treated with at least twice the volume of 20% sodium hydroxide, and the neutral oils are removed either by distillation with steam, or by extraction with a suitable solvent (benzene). The soda solution is then acidified and the tar acids examined for phenol as usual.

An interesting paper dealing with phenol in cresylic acid has been published by Knight, Lincoln, Formanek, and Follett (J. Ind. Eng. Chem., 1918, 10, 9; this J., 1918, 85 A), in which a method is described whereby reference to graphs is claimed to be obviated. These workers also make use of *o*-cresol, and there is no doubt the method eliminates the possibility of estimating some of the *o*-cresol as phenol. Where large numbers of samples have to be dealt with, the method is too lengthy for general use. Our method of utilising *o*-cresol is rather different from that of Knight, Lincoln, Formanek, and Follett. We endeavour to procure a distillate up to 195° C. which shall contain *o*-cresol as the main constituent of the cresols which distil over up to this point. Having regard to the close agreement between the solidifying points of prepared mixtures of the pure cresols with those obtained with representative distillates from commercial cresylic acid (see table of solidifying points, this J., 1917, 842) it seems probable that the composition of the distillate up to 195° is, in these cases, as uniform as can be expected as regards the cresols. What the actual composition of this distillate may be is not known with any certainty, but two of the constituents can be determined, namely the phenol by our process and *m*-cresol by Raschig's nitration method. This leaves *o*- and *p*-cresol undetermined. From certain data in our possession it may be found possible to determine these two cresols, at least approximately, but in the present circumstances there is no opportunity of dealing with the matter adequately.

There is one point in connection with all methods requiring specific gravity and solidifying point determinations of phenols to which we desire to call particular attention. The phenols must be dried before the determinations are made. Distillation

alone is insufficient to remove all the water, and the influence of small quantities of water, particularly on the solidifying points, is very marked. It is not unlikely that the different melting and solidifying points of the cresols recorded by various workers are largely due to the presence of minute quantities of water.

While this paper was being written, a communication on the subject by G. H. Sharples appeared (this J., 1918, 109 T). This paper clearly brings out the effect of small quantities of water on the solidifying point and the specific gravity.* Sharples recommends the addition of *o*-cresol at an early stage to ensure the presence of sufficient *o*-cresol and also to avoid one of the fractionations. This modification certainly shortens the process considerably.

Short method for the examination of cresylic acid for phenol. For this test the pure tar acids are required. Neutral tar oils, naphthalene, and bases, if present in more than traces, must be removed by steam distillation of the solution in sodium hydroxide, or by treatment of the solution by means of benzene or ether. The recovery of the tar acids from the soda solution is effected by acidification with sulphuric acid, care being taken to extract the acid layer so as to recover any phenol present in the sodium sulphate solution.

The tar acids are dried by means of ignited calcium chloride and distilled in the distillation apparatus shown in the figure.

This distillation apparatus has the dimensions shown in the figure and is the most convenient form to use. If long-necked flasks of the dimensions shown are not available, then a short-necked flask with a body of the same size may be used. The thermometer should be accurately calibrated

* Paterno and Ampola (Gazz. Chim. Ital., 1897, 27, 523) have shown that the effect of 0.5% of water is to lower the solidifying point of phenol about 2° C. Similar results are found with the cresols.

between 90° and 250° C. and should have divisions of at least 0.5°.

The apparatus is best supported by three clamps, one attached to the flask and inserted through the slot in the cylinder for flame protection as indicated, a second about halfway up the fractionating column, and the third to support the condenser and fixed about midway between the top of the receiver (100 c.c. graduated cylinder) and the bend.

Rubber should not be used in the construction of the apparatus, as hot cresols gradually dissolve rubber. Ordinary cork stoppers are satisfactory but they must be renewed frequently.

100 c.c. of the thoroughly dried tar acids is distilled at the rate of 7 c.c. per minute, and the fraction (A) boiling up to 210° C. is collected. This fraction is redistilled at the same rate, and the portion (B) boiling up to 202° C. is collected. If this does not exceed 5%, the sample is satisfactory (i.e., does not contain more than 5% of phenol) and no further test is required. When more than 5% is obtained, the fraction (B) is redistilled and the portion boiling up to and including 195° C. is collected separately and tested for phenol by taking its specific gravity at 15.5° C. and by means of bromine water.

Specific gravity. This is best taken in a pycnometer, or more expeditiously by means of a Westphal balance if enough distillate is available. The specific gravity may be taken at any convenient temperature and the necessary correction applied from the following table to bring the result to 15.5° C. The correction for specific gravity is given by the formula $(t-15.5) \times 0.00055$, where t is the temperature of the experiment. The correction factor is the mean of the actual values from large numbers of distillates. Very few distillates give results varying by more than 0.00002 from this mean factor.

Correction for specific gravity

°C.	Correction	°C.	Correction
10	-0.0030	20	+0.0025
12	-0.0019	22	+0.0036
14	-0.0008	24	+0.0047
15	-0.0003	26	+0.0058
16	+0.0003	28	+0.0069
18	+0.0014	30	+0.0080

Bromine water test. For this test a freshly prepared saturated aqueous solution of bromine is required. 0.1 to 0.2 c.c. of tar acid distillate is placed in a glass cylinder of about 100 c.c. capacity. About 10 c.c. of water is added, and then two or three drops of hydrochloric acid (sp. gr. 1.15). The mixture is well shaken and sufficient bromine water is added to bring the total volume to about 100 c.c. The cylinder is again vigorously shaken and the precipitate allowed to settle. If 5% of phenol or more was present in the original sample, a voluminous light precipitate is formed, which is better observed after the liquid has been allowed to settle for about 15 minutes. The cresols alone produce only a dark oil or a heavy granular precipitate which settles quickly. If the bromine precipitate is examined under the microscope (magnification 100) the phenol precipitate is seen to consist of small needles, and is quite distinct in appearance from the cresol compounds.

It is desirable to make up a few mixtures of phenol and cresols so as to become acquainted with the nature of the precipitate. With a little practice the phenol precipitate is unmistakable.*

If the specific gravity at 15.5° C. exceeds 1.048 and a decided phenol precipitate is obtained with bromine water, then the proportion of phenol must be determined by the process previously described (this J., 1917, 843). In applying this process corrections for barometric pressure and emergent stem should be made as in the shorter method here described. If the specific gravity is 1.048 or less and the bromine precipitate is not characteristic of tribromophenol, the sample may in general be considered to contain less than 5% of phenol.

Corrections for the portion of the stem of the thermometer not immersed in the vapour and for barometric pressure are calculated from the following formulae.

TABLE I.

Correction for emergent stem. $0.000143(T-t)N$.

T is observed boiling point.

t is the temperature of the middle point of the portion of the stem outside the vapour.

N is the number of degrees of the stem outside the vapour.

Table of corrections to be added for values of $(T-t)$ and N .

THE SOLIDIFYING AND BOILING POINTS OF PHENOL AND THE CRESOLS.

BY J. J. FOX, D.SC., F.I.C., AND M. F. BARKER, B.SC., A.I.C.

Some time ago the authors were called upon to devise a method for the detection and estimation of small quantities of phenol in cresylic acid. One of the first things necessary in the investigation of mixtures of closely related substances such as phenol and the cresols, is to possess a complete record of the variation of the physical properties of such mixtures with the composition. The complete curves for mixtures of phenol and the cresols have not been recorded so far as the authors are aware. A large amount of work on mixtures of phenol and cresols has been done by Weiss (see this *J.*, 1913, 692, and also Weiss and Downs, this *J.*, 1917, 863), and tables are referred to in Lunge's "Coal Tar and Ammonia," but the information was insufficient for our purpose.

The results we have obtained with the purest cresols available in the large quantities needed for this class of work are important, whether they are considered from the point of view of the valuation of carboic acid or on theoretical grounds.

In judging of the purity of the materials used, we have considered those samples as the best which furnished results for specific gravity and boiling point most nearly in agreement with the values recorded by W. H. Perkin (*J. Chem. Soc.*, 1896, 69, 1182), because Perkin's values can only be obtained after suitable purification and drying. With substances giving Perkin's constants the highest solidifying or melting points are obtained.

The constants that we have obtained for cresols and phenols have been given in an earlier paper

(this J., 1917, 842). Where necessary we have utilised Perkin's data for the specific gravity of phenol at various temperatures.

To obtain materials having the constants specified the following methods of purification were adopted.

Phenol. "Absolute" phenol of commerce was distilled, the first fractions containing a little water being rejected. At 182.5° C. the temperature remained constant and the middle fraction was collected for use. This fraction was further dried by keeping it in the liquid state over ignited calcium chloride for several hours. The resulting phenol had a freezing point of 40.5° C. when freshly prepared and dry.

o-Cresol. Commercially pure o-cresol was dissolved in excess of 20% sodium hydroxide, diluted with water, and the liquid distilled with steam to remove naphthalene, tar oils, and bases. The resulting soda solution was acidified with sulphuric acid, and the cresol layer removed and washed with water until free from sulphuric acid. The water was separated as completely as possible and the cresol was distilled. The first fraction distilling over was rejected, the portion boiling between 191° and 192° C. being collected. This fraction was dried over ignited calcium chloride and redistilled, the middle portion of constant boiling point being used. It had a freezing point of 30.0° C. and sp. gr. at 15.5° of 1.0512. By collecting the middle 50% alone, we had no difficulty in preparing o-cresol with the solidifying point mentioned.

m-Cresol. A supply of Kahlbaum's m-cresol was available and this was found satisfactory when redistilled. Larger quantities were obtained by Raschig's process (Ger. Pat. 114,975) from commercial m-cresol. The redistilled m-cresol was heated in a large flask with 4 times the weight of strong sulphuric acid (as described by Raschig) at 100° C. for about one hour. The acid was diluted with water, steam was passed in and the liquid was heated until a temperature of 125°–127° C. was reached. The heating of the flask was regulated to maintain this temperature, at which decomposition of the m-cresol sulphonic acid results, and the m-cresol passes over with the steam. It is sometimes coloured yellow by this treatment, but although the colour persists it does not in any way affect the physical properties of the m-cresol. The cresol was purified by redistillation after drying over calcium chloride, the fraction boiling between 202.0° and 202.5° C. being collected and redistilled. Our preparation, as well as Kahlbaum's (when dried and redistilled), solidified at +2.4° C. and had a sp. gr. of 1.0387 at 15.5° C. The success of this method of purifying m-cresol depends on preventing the temperature to which the sulphonic acid is heated with steam rising much above 125° C. If the m-cresol is not thoroughly dried it will not solidify. Slight variations in the boiling point were observed with different specimens.

p-Cresol. A large quantity of commercially pure p-cresol, freed from tar oils, etc., was repeatedly liquefied, frozen, and drained on gauze from adherent liquid. The solidified portion was then liquefied and distilled, the first portion of the distillate being rejected. The dried cresol had sp. gr. 1.0288 at 15.5° C. and froze at 36.0° C. The purification of the cresols leads to considerable waste of material, hence it is desirable to operate on several kilos.

The constants found by us differ a little from those given by Knight, Lincoln, Formanek, and Follett (J. Ind. Eng. Chem., 1918, 10, 10) the freezing points for o- and p-cresol being higher than those given by these workers, but we prefer them for the reasons mentioned above. It might be added that o-cresol prepared from pure o-toluidine was never in our experience so good as the o-cresol

obtained by working up several kilos. of the best commercial o-cresol available.

Specific gravities were taken in a capped silica Sprengel tube holding about 30 c.c. and also in a pycnometer holding 50 c.c.

The freezing points were determined in an apparatus of the Beckmann type as used for molecular weight determinations. Open-scale thermometers divided in tenths of a degree were used. The mercury thread was arranged so that one degree at most was visible above the top of the freezing point tube. This was secured by changing the thermometer according to the temperature to be read. The bulb of the thermometer was always well immersed in the liquid and the same quantity of liquid, as nearly as possible, was used for each determination. The freezing point tube was surrounded by an air bath, at the bottom of which some dry calcium chloride was placed to keep the air dry. This also stopped the formation of mist and so prevented the view of the contents of the vessel being obscured. The cresol mixture was stirred by means of a spiral wire stirrer, and moisture was prevented from gaining access to the freezing point tube by attaching a calcium chloride drying tube to the side tube of the apparatus. The air bath was surrounded by an outer jacket, containing water for the freezing point temperatures of 20° C. and higher, ice and water for temperatures of 10° C. and lower, and salt and ice for the lowest temperatures. The contents of the outer jacket were stirred with a stout wire stirrer. As excessive supercooling must be avoided, the temperature of the outer bath should be as near as possible to that of the freezing point expected, generally within 2° or 3° C. At the freezing point the temperature rises to a maximum and remains constant for some time. There is no difficulty in obtaining readings of the freezing point accurate to less than 0.1° C. It might of course be possible to obtain greater accuracy by the use of other means of recording the temperature, but the results actually obtained are sufficient for use. In the cases where considerable supercooling might occur, accurate freezing points could only be obtained by keeping the temperature of the outer jacket as close as possible to the freezing point, and also by adding a crystal of one of the constituents.

The apparatus used for the boiling point determinations consisted of a flask practically identical with that described by Northall-Laurie (Analyst, 1915, 40, 386) fitted to a condenser. By means of this device the condensed liquid flows back into the boiling liquid, so that by careful regulation of the heating to prevent violent ebullition, the composition of the boiling liquid remains practically unchanged. For determining boiling points above or below atmospheric pressure, the top of the condenser was attached to a mercury manometer and air reservoir, which contained about 20 litres of air. This acted as a "cushion," and connection with the condenser was made by a T-piece and suitable taps, so that any part of the apparatus could be isolated. Air was pumped out of or forced into the reservoir and the reservoir tap was then turned on slowly to equalise the pressure throughout the apparatus. When this had occurred the boiling was commenced. It was found that with a reservoir of the dimensions given, the manometer and temperature indications were readily kept constant for a considerable time, and for each pressure observations could easily be made over an interval of at least 20 minutes. This is sufficient time to permit the conditions to become uniform and to obtain equilibrium. In every case, drying tubes containing freshly ignited calcium chloride were interposed between the air reservoir and the T-piece.

It is convenient to consider the boiling point and freezing point curves together.

Phenol and o-cresol give a continuous freezing point curve (Fig. 3). There are no breaks, and a minimum freezing point results with nearly equimolecular proportions of the two constituents. There is no clear eutectic point and no evidence of the formation of compounds. The boiling point curve (Fig. 6) is almost a straight line lying between the boiling points of the separate constituents.

Phenol and m-cresol. This freezing point curve (Fig. 1) is the most complicated and at the same time is of the greatest interest. It exhibits two minima, one at -4°C . with 10 mols. %, and one at $+10.2^{\circ}\text{C}$. with 50 mols. % of phenol. A well defined maximum point occurs at $+17^{\circ}\text{C}$. with 33.3 mols. % of phenol. The latter point is noteworthy as it corresponds with a compound of phenol and *m*-cresol represented by $\text{C}_6\text{H}_5\text{OH} \cdot 2\text{C}_7\text{H}_7\text{OH}$. The form of the curve is that of many other freezing point curves of binaries and it has two eutectic points. That at -4°C . results from the freezing point curve of *m*-cresol and the compound

and that at $+10.2^{\circ}\text{C}$. from the freezing point curve of this compound and phenol. It is difficult to avoid the conclusion that the compound of *m*-cresol and phenol is stable under the conditions described. The boiling point curve of phenol and *m*-cresol is not a straight line, but deviates from a straight line in the well-known manner of other mixtures of completely miscible liquids.

p-Cresol and phenol. This curve (Fig. 1) has two branches meeting at 50 mols. % where the eutectic point occurs. Lunge obtained similar results. The

FIG. 1.

I. Phenol and *m*-cresol. II. Phenol and *p*-cresol.

boiling point curve of phenol and *p*-cresol is similar to that of phenol and *m*-cresol.

The freezing point curves for the cresols taken in pairs are shown in Figs. 2 and 3. Again *m*-cresol furnishes the most complicated curves. With *m*-cresol and *p*-cresol an undoubted but small maximum point results with about 20% of *p*-cresol and the eutectic occurs with the 50% mixture (Fig. 2). The form of this curve suggests the existence of a second eutectic very close to pure *m*-cresol, but we could not find the point with our apparatus.

The curve for *o*-cresol and *m*-cresol is a complex one, and recalls that of *m*-cresol and phenol. While there are two undoubted breaks in this curve with 40% and 80% of *m*-cresol, there is no well-defined

maximum between the breaks, and the existence of a compound of *o*-cresol and *m*-cresol cannot therefore be inferred.

FIG. 2.

I. Ortho-cresol and para-cresol. II. Meta-cresol and para-cresol.

No very deep study of the freezing point curves is necessary to emphasise their great practical importance when considering methods for the valua-

tion of carboic acid, such as Lowe's method. The outstanding fact is that many different mixtures of

FIG. 4.

I. *o*-Cresol II. Phenol.

phenol and the cresols have the same solidifying point. Furthermore, mixtures containing large proportions of phenol may have very low melting points. This is clearly shown by drawing a horizontal line through the point 10°C . in Fig. 1. It is unsafe in practice to consider cresylic acid free from phenol simply because it yields a distillate which does not freeze when immersed in ice water. The bearing of these observations on the possibility of separating phenol from the cresols by freezing is evident.

FIG. 5.

● *p*-Cresol.× *m*-Cresol.

Expressed in figures, the value of dt/dp for phenol and the cresols for the whole range of the curve is, phenol 0.059, *o*-cresol 0.065, *m*-cresol 0.059, *p*-cresol 0.061. *o*-Cresol gives the outstanding curve of these four, the other three being nearly parallel. The results may be put in another way and one of which the application in practice is important.

When it is desired to correct the boiling point of the cresols for pressure in the ordinary determination of the boiling point, the general formula

$$\theta = C(760 - p) \times (273 + t)$$

is used (Young's "Fractional Distillation," 1903, p. 14); where θ is the correction to be added or deducted, and p and t are the observed pressure and temperature. C has the following values:—phenol 0.000101; *o*-cresol 0.000126; *m*-cresol 0.000103; *p*-cresol 0.000103. The high value of " C " for *o*-cresol, which is quite outside the limits due to experimental errors, might be taken as some evidence that the substance possesses a simpler molecule than the other phenols, and in fact Hewitt and Winnill have shown that *o*-cresol is the least associated of the cresols and phenol (Chem. Soc. Trans., 1907, 91, 441).

Fig. 6 shows the boiling points of mixtures of phenol with the cresols and furnishes a good illustration of the general rule that with mixtures of closely related substances, the boiling point curve departs less from a straight line as the difference between the boiling points of the components diminishes. Following Young's nomenclature (*loc. cit.*), if the boiling point curve for any pair of substances is a straight line, the formula

FIG. 6.

I. Phenol + *m*-cresol. II. Phenol + *p*-cresol. III. Phenol + *o*-cresol.

The boiling point curves showing the variation of boiling point with pressure (Figs. 4 and 5 and table) are almost straight lines. Those for *m*- and *p*-cresol almost coincide, as the boiling points of these two substances are only about 1°C . apart throughout the range of pressures examined.

$t' = t_n + 0.01m\Delta$ applies. In this case t_n is the lower boiling point, m is the molecular percentage of the higher constituent, Δ the difference in boiling points between the constituents, and t' is the calculated boiling point of the particular mixture under consideration. If the difference between the calcu-

MR. H. G. SMITH IN THE CHAIR.

THE USE OF THE REFRACTOMETER IN THE EXAMINATION OF EUCALYPTUS OILS.

BY HENRY G. SMITH, F.C.S.

It is now recognised that the determination of the physical properties of essential oils is of considerable value in their classification and investigation. The various oils obtainable from the eucalypts are, in most cases when true to species name, equally well controlled in this way, and of all the physical tests applicable for the purpose, that of refractive index is not the least valuable.

A relative constancy in the character of the oils of identical species of eucalyptus, growing under natural conditions, has been shown, and abundant evidence has accumulated on this point. Only in a very few instances does distinct local variation occur, and even with these species the reasons for this departure are fairly well understood, the selective peculiarities of the species themselves being perhaps the most important factor in this connection. No absolute constancy can, of course, be expected with plant products—essential oils particularly—as these are aggregates of constituents, each having its own physical constants. With the eucalypts this particular fact might suggest a difficulty in securing fairly concordant results on account of the diversity of constituents in the genus, but experience has shown that this is not so and the instances given below illustrate this clearly.

The methods of extraction of eucalyptus oils in Australia have improved considerably during recent years, and greater care is now taken in the selection of material from desired species; consequently the oil is more constant in character, and the steam-rectified product remarkably uniform in physical properties.

It is becoming customary to sell the oil from a particular eucalypt by its species name, as for instance, *Eucalyptus polybractea*, *E. Smithii*, *E. dives*, *E. Macarthurii*, and so on, and in this way it is possible to secure the desired uniformity in the product. When the advantages of this method become fully recognised and more extensively followed, the industry will be at a considerable advantage, and the practice of mixing oils from different species in order to meet a particular standard will become quite unnecessary.

Not only is the refractometer useful in controlling the oils themselves, but it is also the means of indicating the presence of previously undetected

constituents. It was in this way that butyl butyrate was found, first in the oil of *Eucalyptus Perriniana* (Proc. Roy. Soc., N.S.W., Dec., 1914). The abnormally low refractive index (1.4538 at 10° C.) of the lower boiling fraction suggested the presence of an unrecognised constituent in eucalyptus oils. This ester has since been shown to be a common constituent in the oils of allied species, not only from those common to Eastern Australia but from those of Western Australia also, localities thousands of miles apart.

The principal species now worked most extensively in Eastern Australia are, (1) *Eucalyptus polybractea*, the "Blue Mallee" of New South Wales, and the "Silver Leaf Mallee" of Victoria; (2) *Eucalyptus australiana*, the "Narrow Leaf Peppermint" or "Messmate" of New South Wales; (3) *Eucalyptus dives*, the "Broad Leaf Peppermint" of New South Wales and Victoria.

The figures tabulated below give the physical properties of the oils of these three species commercially distilled from material true to name, and during a considerable period of time:—

Eucalyptus polybractea.

Type of oil and date	Sp. gr. at 15° C.	Rotation α_D	Refractive index at 20° C.

* This oil was from Bendigo, Victoria; all the others were from Wyalong, N.S.W.

It will be noticed that two of these samples were levorotatory. This is due to the influence of a small quantity of the optically active aromatic aldehyde aromadendral. The optical rotation of the oil of this species is but small at any time, and although mostly dextrorotatory, occasionally shows levo-rotation. This result in no way interferes with the quality of the oil, and is not due to phellandrene. The American objection to a levorotatory eucalyptus oil is, in this case, not warranted, and should not be persisted in. Considerable quantities of the oil of this species are now being sent to America, and I would suggest that the refractive index is a more satisfactory means of control than that of optical rotation, particularly as the oil is usually recently distilled when it leaves Australia.

The oil of this species is one of the richest in cineol content, and this is indicated by the low refractive index. The solubility in alcohol (79% by weight) of the steam-rectified oil is from 1.65 to 1.1 volumes and is remarkably constant.

Eucalyptus australiana.

This species was, prior to the investigation of the Tasmanian eucalypts by Mr. Baker and myself

(Roy. Soc. Tasmania, Oct., 1912), considered by botanists to be *E. amygdalina*, but the Australian tree has now been raised to specific rank. During the last three or four years considerable quantities of a high-class eucalyptus oil have been distilled from it in the Nerrigundah and Yowrie districts of New South Wales. In the "Research of the Eucalypts," Baker and Smith, 1902, p. 170, it was shown that by fractional separation at stated times during the primary distillation, the oil which came over during the first hour was much the richest in cineol. The yield of oil is also greater from this species than from other eucalypts. It is thus possible to adopt this mode of procedure. The species appears to have broken away from its natural habitat on the highlands and established itself at lower altitudes, where the phellandrene has practically disappeared, the cineol increasing to a corresponding extent (see Baker and Smith, Proc. Roy. Soc. N.S.W., Dec., 1915). In the above-mentioned districts the oil is now commercially separated at the end of the first hour, and contains about 70% of cineol or over; it is sold for pharmaceutical purposes. The remainder, which comes over during the later distillation, is utilised for the separation of minerals by flotation or for other purposes.

The constancy of the physical characters of the first-hour oil can be judged from the following figures, those of refractive index being in remarkable agreement.

Eucalyptus australiana of New South Wales.

First-hour oil.

Place and date	Sp. gr. at 15° C.	Rotation α_D	Refractive index at 20° C.
Nerrigundah, 1913 ..	0.9188	+0.3°	1.4621
Norrigundah, 1913 ..	0.9193	+0.9°	1.4628
Yowrie, 1913	0.9186	+0.5°	1.4624
Yowrie, 1913	0.9195	+0.4°	1.4622
Nerrigundah, 1914 ..	0.9193	+1.5°	1.4631
Yowrie, 1914	0.9199	+0.1°	1.4622
Yowrie, 1914	0.9202	-1.2°	1.4636
Nerrigundah, 1914 ..	0.9195	+1.4°	1.4631
Reedy Creek, 1915 ..	0.9196	+1.2°	1.4625
Yowrie, 1916	0.9193	+1.3°	1.4626
Belimbria, 1917 ..	0.9186	+1.7°	1.4617
Yowrie, 1917	0.9205	+1.6°	1.4635
Wyndham, 1917 ..	0.9220	+0.7°	1.4635

Second-hour oil.

Yowrie, 1917 ..	0.9096	+2.0°	1.4710
Norrigundah, 1917 ..	0.9160	+3.6°	1.4711

In the majority of cases the optical rotation is slightly to the right but occasionally the oil is levorotatory. This is due to the presence of a small proportion of phellandrene, but this is not detrimental to the quality of the oil. The value is indicated by the refractive index, which only shows a very slight increase over the dextrorotatory samples.

With the second-hour oil the refractive index is higher, and in this the cineol does not usually exceed a fourth of the amount present in the first-hour oil.

As the monetary value of the first-hour oil is about double that of the remainder, it may be necessary to adopt a somewhat rigid standard in order to maintain the quality of the first-hour oil.

The ready solubility in alcohol of the oil of *E. australiana* is particularly noticeable, even if distilled at high altitudes when phellandrene will be present and the rotation -12° to -15°. With the first-hour oil from the Nerrigundah and Yowrie districts the solubility is equal to that of *E. polybractea*, and is remarkably constant.

Eucalyptus dives.

The oil of this species, when freshly distilled, shows a corresponding relative constancy in constituents and physical properties, as is noticeable with other species of eucalyptus. The oil of *E. dives* consists principally of levorotatory phellandrene, has a high optical rotation, and contains, as a rule, less than 5% of cineol. Much of the oil of this species has reached Europe as the product of *E. amygdalina*. This was to a certain extent excusable, because *E. dives* was formerly classified as a variety of *E. amygdalina*, and varietal names seem soon to lose their significance.

The oil of *E. dives* is considered to be the best of all essential oils for mineral separation by flotation, and considerable quantities are now being used in Australia for that purpose. The species has a most extensive range in Eastern Australia and gives about a 3% yield of oil from freshly cut material.

When freshly distilled the levo-rotation is very high, as is also the refractive index. The tendency among distillers is now to distil the leaves of this species for several hours in order to obtain all the available oil from the leaf. The oil from this extended distillation has naturally a higher specific gravity than that of the oil from, say, a four hours' distillation, but for the purposes for which the oil is employed both are of equal value.

The following figures were obtained with the crude oils from the various localities, which are in some instances wide apart. The oils were all commercially distilled.

Eucalyptus dives, New South Wales.

Place and date	Sp. gr. at 15° C.	Rotation α_D	Refractive index at 20° C.
Cooma, 1913	0.8928	-61.3°	1.4803
Colombo, 1914	0.8976	-62.3°	1.4803
4 hours' distillation, Mongarlowe, 1916 ..	0.8892	-69.8°	1.4798
8 hours' distillation, Mongarlowe, 1916 ..	0.9004	-63.9°	1.4811
Colombo, 1916	0.9020	-55.4°	1.4808
Mongarlowe, 1916 ..	0.9011	-59.3°	1.4806
Braidwood, 1916 ..	0.9001	-56.7°	1.4809
Orange, 1916	0.8950	-61.2°	1.4805

It is apparent that the determination of the refractive index of the oil of this species is of considerable value in its control.

The refractometer employed was a Zeiss-Abbé instrument with water-jacketed prisms, and for correction the figure 0.00047 was employed. For correcting the specific gravity the figure 0.00075 was used.

NOTES ON CINEOL.

BY J. C. EARLE, F.I.C.

Solubility in water. The solubility of pure cineol at various temperatures was determined in an apparatus of the type devised by Farrington for the determination of fat in skim milk by the Babcock test (see Snyder, "Dairy Chemistry," p. 26). The following results were obtained:—

Temperature, °C.	Solubility, grms. of cineol in 100 grms. water.
1.5	0.64
7.5	0.57
10	0.54
21	0.35
40	0.21
50	0.19

Detection of cineol by the iodol method. A few tests were made to determine the sensitiveness of the iodol test for cineol. Various mixtures were made of pure cineol with a phellandrene oil containing no cineol. One c.c. of the oil under examination was warmed in a nearly boiling water-bath, the warm oil was saturated with iodol and filtered through a small paper into a watch-glass. Crystals of the double compound of cineol and iodol developed in the filtered oil immediately when one vol. of cineol was mixed with 3 vols. of phellandrene oil; on standing for a short time with 10 vols. of phellandrene oil, and after standing for half an hour with 20 or 30 vols.

Communications.

RESIDUAL AND EXTINGUISHING ATMOSPHERES OF FLAMES.*

BY THOMAS FRED ERIC RHEAD.

When a jet of combustible gas or vapour is allowed to burn in air in a closed vessel, the flame gradually alters in character as the oxygen diminishes, and finally goes out. The atmosphere remaining after the flame has been extinguished is usually termed the "residual atmosphere"; such an atmosphere contains, besides oxygen and nitrogen, the products of combustion of the combustible gas.

On the other hand, a mixture of oxygen and some "inert" gas, such as nitrogen or carbon dioxide, can be prepared so that it is just unable to support the combustion of a combustible gas introduced into it. Such a mixture is termed an "extinguishing atmosphere."

The research described in this communication had as its main object the determination of the oxygen contents of the residual and extinguishing atmospheres for flames of various gases, the inert gas employed for the extinguishing atmosphere being nitrogen.

Several investigators have approached the problem from the point of view that the oxygen content of the residual and extinguishing atmospheres of a flame should have the same value, and that this value represents a physical constant for that flame.

Their results for methane, hydrogen, and carbon monoxide are as follows:—

TABLE A.

Investigator	Oxygen content of residual atmosphere			Oxygen content of extinguishing atmosphere		
	Me- thane %	Hy- drogen %	Car- bon mon- oxide %	Me- thane %	Hy- drogen %	Car- bon mon- oxide %
Clowes and Feil- mann*	15.6	5.5	13.35	17.4	6.3	15.1
W. P. Jerissen and N. H. Sie- wertz von Reesemat†	—	4.0	11.2	—	3.5	10.0
J. Ilarger‡	17.5	7.5	—	—	—	—

* This J., 1894, 1155.

† Chem. Weekblad, 1909, 6, 1053; see this J., 1910, 478.

‡ "Coal Mine Explosions" (1913).

The lack of agreement in the above results is probably due to differences in experimental conditions.

In order that a flame may be maintained when a stream of combustible gas issues into an atmosphere of oxygen and an inert gas (nitrogen) at ordinary temperature and pressure, a mixture of the gas with the atmosphere must be produced in sufficient quantity, which, when ignited, will self-propagate flame at a rate equal to the rate of flow of the mixture. For any particular combustible gas there exists a range of such mixtures in which flame can be propagated at rates rising from zero to a maximum and again falling to zero, as the mixtures used contain increasing percentages of combustible gas. As the oxygen content of the mixture is decreased the range is considerably reduced, until finally only one particular stationary mixture at ordinary temperature and pressure will just propagate flame.

Burgess and Wheeler (Chem. Soc. Trans., 1914, 105, 2591—2605; this J., 1914, 1195) found that for methane the mixtures with air which would propagate flame ranged from 5.6 to 14.8% methane, and Parker (Chem. Soc. Trans., 1915, 107, 328—337; this J., 1915, 482) obtained the following figures for the initial rate of propagation of flame in the intermediate mixtures (*i.e.*, the rate of the "uniform movement"):—

Percentage of methane in air	Rate of propagation of flame, cm. per sec.
6	53
7	69
8	85
9	102
10	107
11	198
11.7	76

On reducing the oxygen content of the mixtures, Burgess and Wheeler (Chem. Soc. Trans., 1914, 105, 2598) reached the limit of 13.25 to 13.45% of oxygen, below which no variation in the proportions of methane and nitrogen would give stationary mixtures capable of self-propagating flame.

If a combustible mixture is caused to flow along a tube at a rate equal to the initial rate of propagation of flame in that mixture the flame will appear to be stationary, but if the gaseous flow be increased the flame will travel in the direction of that flow until it is projected into the air, where it will be extinguished, because the mixture is destroyed by dilution with air.

Immediately a stream of combustible gas emerges into an atmosphere of oxygen and nitrogen, intermediate mixtures begin, and all ranges of mixtures are produced between the limits of 100% gas on the

* Publication of this paper on the results of work carried out prior to the war, has been withheld until now because the author hoped to complete it, but has been continually prevented by war conditions.

one hand and 100% atmosphere on the other hand. One particular mixture will propagate flame at a maximum rate, and consequently it will be possible to maintain a flame with increasing velocity of gas stream, until the rate of travel of this mixture is just greater than the maximum rate of flame propagation. If, however, the oxygen content of the atmosphere be reduced, the range of mixtures of combustible gas and atmosphere which will propagate flame against the flow of the mixtures is also reduced, and a point is reached at which no mixture of gas and atmosphere is formed, in which the rate of flame propagation balances the flow of the mixture, consequently the flame is extinguished and the atmosphere represents the so-called extinctive atmosphere of that flame under the conditions existing.

The mixture which will just maintain flame against its own flow must of necessity be richer in oxygen than the stationary mixture which contains the lowest percentage of oxygen just to propagate flame. The same observation holds in the case of a gas burning to extinction in an enclosed volume of air at ordinary temperature and pressure, except that in this case the "residual" atmosphere contains products of combustion—usually carbon dioxide, which affects the flames rather differently than nitrogen.

A stream of combustible gas, issuing into an atmosphere of oxygen and nitrogen, mixes with that atmosphere through two main causes: (1) The interdiffusion between the gas and atmosphere, and (2) the mechanical mixing effected by the orifice or jet supplying the gas.

The maintenance of a flame in the mixtures so produced depends upon:—

(1) The rate of propagation of flame in the mixtures, involving (a) the number of molecules of oxygen concerned in the combustion of one molecule of gas. (b) The calorific value of the gas. (c) The conductivity and specific heats of the combustible gas, oxygen, nitrogen, and products of combustion. (d) The rate of radiation of heat

Under the most favourable experimental conditions the oxygen content of the residual or extinctive atmosphere left by flames of different combustible gases burning in air will depend primarily upon the rate of diffusion of the gas, and the effect of this will be increased or decreased according as the reaction is simple or complex, and according as the initial rate of flame propagation in the mixtures is great or small. For example, in the case of hydrogen (the residual atmosphere of the flame of which contains about 5.6% oxygen) there is a high rate of diffusion, a simple reaction, and a high initial rate of flame propagation in its mixtures with air, but in the case of methane (which gives a residual atmosphere containing about 16.0% oxygen) the rate of diffusion is much slower, the reaction more complex, and the rate of flame propagation smaller.

EXPERIMENTAL.

Residual atmospheres.

The chief difficulty met with in determining the residual atmosphere of a flame is that caused by the hot products of combustion heating the contents of the vessel and so enabling the flame to burn longer than it would do if the contents remained at the room temperature. For a flame of constant size this error is likely to be less in a large vessel than in a small one, because the products have a longer time to cool before they come into contact with the flame again. Even with a large vessel this difficulty is experienced if the flame is sufficiently large, because when nearing extinction the flames of some gases rise above the jet and burn in the heated atmosphere at the top of the vessel.

Experiments were carried out in two apparatus, one of 1½ litres capacity and one of 12 litres. Most of the results in the smaller apparatus were vitiated by the heating of the contents by the flames.

The 12 litre apparatus (Fig. 1) consisted of an inverted aspirator bottle with a jet placed axially 3 in. from the bottom and fitted with electrical ignition. Samples were taken simultaneously from the top and bottom of the apparatus, and, although no mechanical method of circulation was resorted to, these samples showed very little difference in oxygen content. The top sample contained approximately 0.25% less oxygen than the bottom sample, unless flames over 1½ in. high were used, in which case wider differences occurred between the two samples. All analyses were carried out in a Bone and Wheeler gas analysis machine. The bottom sample, taken 2 in. above the jet, was recorded as the residual atmosphere. Temperatures taken by means of thermometer B at the side of the jet 1 in. away showed a rise in temperature of only one or two degrees during the experiment,

FIG. 1.

from the flame. (e) The diathermancy of the gases. (f) The ignition temperature of the gas in the atmosphere concerned. (g) The rate of diffusion of the gases. (h) The effect of temperature on the rates of the chemical reactions involved.

(2) The rate of flow of the combustible mixtures away from the orifice, involving the rate of flow of the stream of combustible gas.

(3) The size of the flame, involving the area over which combustion is taking place and the amount of combustible mixture produced in unit time.

(4) The cooling effect (and possible catalytic effect) of the orifice when the flame remains at that point.

therefore unless the flames rose to the top of the vessel they would not be appreciably sustained by any heating of the contents of the vessel.

The pressure was maintained at that of the atmosphere by allowing some gas to escape (1 or 2% by volume of the enclosed atmosphere) at the beginning of the experiment through H dipping into a water seal. Preliminary experiments using a pressure gauge had shown that expansion of the atmosphere only occurred at the commencement of an experiment, and that from then, right to extinction very little variation in pressure took place, until the flame went out, when a rapid fall in pressure set in.

The influence of the size of the flame was first determined, employing pure methane. Using a glass tube jet 4 mm. internal diameter, and varying the rate of the gas stream to give flames of different sizes, the following results were obtained:—

Initial height of flame, cm.	Oxygen in residual atmosphere, %.
0.6	16.8
3.0	15.6
6.0	14.9

The 3 and 6 cm. flames, when near extinction, travelled to the top of the vessel, where they continued burning for some time in the heated atmosphere, and hence the samples taken near the jet in

the increasing proportion of carbon dioxide produced per volume of oxygen consumed, but this requires confirmation. No carbon monoxide or unburnt gas was detected in the residual atmosphere of methane; the methane had completely burned to carbon dioxide and steam. The methane flame enlarged considerably during combustion and gradually rose as a non-luminous blue cone about 8 in. above the jet, where it finally went out.

In the case of propane the flame increased to about three times its initial size, became non-luminous, rose above the jet, and flickered violently before extinction. The butane flame increased from 2 inches to 6 inches in height, became smoky, and flickered violently towards the end. Owing to its high density some of the gas fell down the sides of the jet and a very slight flame flashed through it. The pentane flame (from a small lamp) decreased considerably from an initial height of 1 inch to about $\frac{1}{4}$ inch, owing presumably to the decreased evaporation consequent on the flame becoming cooler when nearing extinction. The cyanogen flame enlarged from 1 to 3 inches and had a red inner cone surrounded by a blue zone, which was again surrounded at the top by a green cone. It flickered violently before extinction. The blue carbon monoxide flame burned steadily, rose a little

FIG. 2.

these cases do not accurately represent the atmosphere round the flame, but the results seem to indicate that a large flame has a lower oxygen content in its residual atmosphere than a small flame, quite apart from the heating of the atmosphere.

The relative values of the oxygen contents of the residual atmospheres left by the flames of different gases were determined, using a silica open-tube jet of 4 mm. internal diameter, and supplying the gases at the same rate in each case. The initial size of the flame varied from about $\frac{1}{4}$ in. in height in the case of hydrogen to about 2 in. in the case of butane.

Gas used.	Oxygen in residual atmosphere.	
	%	%
Methane ...	15.6	15.4
Propane ...	15.9	15.8
Butane ...	16.0	—
Pentane ...	16.4	—
Cyanogen ...	15.3	15.0
Hydrogen ...	5.7	5.6
Carbon monoxide ...	10.2	—

The slight increase noticeable on ascending the methane series of hydrocarbons is possibly due to

above the jet, and increased in size before extinction. The hydrogen flame increased very considerably in size and became almost invisible, and rose high above the jet before extinction.

Extingtive atmospheres.

The method usually adopted for ascertaining these (plunging the flame into ready-made mixtures and obtaining the correct mixture by the method of trial and error) was considered unsuitable, and an apparatus was devised to study the effect of feeding a flame with mixtures of oxygen and nitrogen. By gradually increasing the nitrogen in the mixture a point was reached at which the flame went out. The mixture of oxygen and nitrogen which just extinguished the flame was recorded as the extinctive atmosphere for that flame under the conditions of the experiment. The method allows of fine adjustment and control, and the flame can be studied in all its phases under varied conditions.

The apparatus used (Fig. 2) consists essentially of two parts: one for making and supplying the atmosphere of desired composition, and the other for observing the effect of that atmosphere on the flame in question. Two large gas holders were filled, one

with air and the other with nitrogen, and connected to the mixer, D. When the graduated taps, E and F, were opened, water flowed into the gas holders from the constant-level reservoirs, H and J, and displaced the air and nitrogen, causing them to pass forward into D. By regulating E and F, a steady stream of air and nitrogen of constant composition passes from the mixer to the combustion chamber, A. With well-made cleanly-drilled water taps, E and F, graduated to pass known quantities of water under constant head, the volumes of air and nitrogen could be very easily adjusted to give any desired mixture which, moreover, could be repeated at will. The connections in the mixer were made of glass tubing 9 mm. internal bore. This mixer was found very efficient for delivering up to four litres of a mixture of oxygen and nitrogen per minute.

By allowing mercury to run out of K, a sample of the atmosphere was obtained for analysis. The glass cylindrical combustion chamber, A, was 2.4 cm. internal diameter and 12 cm. high, and was surrounded by the water jacket, C. During an experiment a steady stream of cold water flowed through C, and the temperature was noted by the thermometer. The combustible gas was supplied at any desired constant rate to the jet, B, from a gas-holder of the same type as those used for supplying the air and nitrogen, and was ignited electrically. A little glass wool packed loosely at the bottom of the chamber, A, served to arrest any upward draught likely to be caused by the tube supplying the atmosphere. In this apparatus the heating effect of the products of combustion on the atmosphere was eliminated.

The experiments were conducted in the following manner: A steady stream of cold water was sent through the water jacket and a stream of air from the air-holder through the mixer and combustion chamber at a rate just sufficient to keep the flame steady at the open-tube jet, B. The nitrogen was then gradually turned on (time being allowed between each increase in nitrogen to wash out the mixer with the new mixture) until the flame just went out, and then, before altering E and F, a sample was taken in K and analysed as representing the extinctive atmosphere.

The velocities of the gas stream and atmosphere were calculated from the diameter of the gas jet and combustion chamber, and the volume of gas and atmosphere passing through per minute.

The following observations were made on the limited number of experiments carried out:—

(1) For a constant speed of combustible gas stream and constant speed of atmosphere the extinctive atmospheres of methane, ethane, propane, and butane were found to be identical. This possibly points to a similar primary reaction in each case.

TABLE C.

Com- bustible	Internal diameter of jet, mm.	Speed of atmosphere, cm. per min.	Speed of gas, cm. per min.	% O ₂ in extinctive atmosphere
Methane ..	4	684	288*	16.6
Propane ..	4	715	288	16.6
Propane ..	3	362	230†	16.3
Butane ..	3	362	230	16.3

* = 36 c.c. per minute.

† = 16 c.c. per minute.

(2) The oxygen content of the extinctive atmospheres of the above gases decreases (within limits) with the increased speed of atmosphere.

It appears that, within certain limits (yet to be determined), if the extinctive atmosphere supplying the flame is to have a minimum oxygen content, it must be supplied at a speed greater than that

of the combustible gas. The minimum speed will depend upon the rate of propagation of flame in the mixture produced.

TABLE D.

Com- bustible	Internal diameter of jet	Speed of atmosphere, cm. per min.	Speed of gas, cm. per min.	% O ₂ in extinctive atmosphere
	mm.			
Propane ..	4	715	288	16.6
Propane ..	4	937	288	15.0
Methane ..	4	684	288	16.6
Ethane ..	4	790	288	15.6
Butane ..	4	822	288	15.3
Propane ..	4	937	288	15.0
Methane ..	3	195	230	18.2
Propane ..	3	362	230	16.3

With a slow speed of atmosphere the oxygen is burnt out too quickly, or what amounts to the same thing, the combustible mixture is formed too slowly, but by supplying the oxygen faster, i.e., by increasing the speed of the atmosphere, the combustible mixture is formed quickly enough to maintain flame. The limit to which the speed of the atmosphere can be increased will be reached when the rate of inflammation in the mixture just balances the upward movement of the mixture.

It is thus seen how an atmosphere, too poor in oxygen to maintain a flame when fed to the latter at a slow speed, may be able to maintain that flame when fed at an increased speed. This tends to invalidate Harger's suggestion of employing in coal mines an atmosphere containing 17% oxygen as a preventative of explosions.

An experiment in the apparatus with ethylene delivered through a 4 mm. jet at a rate of 36 c.c. per min., i.e., 288 cm. per sec. and the atmosphere at 872 cm. per sec., gave an extinctive atmosphere containing 13.3% oxygen.

(3) A coal gas flame behaves quite differently from the paraffin hydrocarbon flames. The oxygen content of the extinctive atmosphere of coal gas appears to be almost unaffected by the speed of the atmosphere, but decreases with the increased speed of the gas stream:—

TABLE E.

Speed of atmosphere, cm. per min.	Internal diameter of jet, mm.	Speed of gas, cm. per min.	O ₂ content of extinctive atmosphere
500	3	514	% 13.2
291	3	514	13.1
253	3	514	13.5
500	3	514	13.2
500	3	1028	12.3

This curious behaviour of coal gas will be more easily understood from the following observations and experiments.

It is always noticed that a coal gas flame near extinction behaves differently from the flame of a pure gas such as methane. When the flame of the latter almost reaches extinction it leaves the jet, and can be made to burn at any distance above the jet (within limits) as a blue cone. On the other hand, a coal gas flame near extinction becomes broken, the top portion disappears, leaving a hollow cup-shaped blue flame on the jet, and some gas escapes unburned.

This phenomenon is probably due to coal gas consisting chiefly of hydrogen and methane, two gases possessing widely different oxygen contents in their extinctive atmospheres, and though there might be sufficient oxygen present to support a hydrogen flame, the methane cannot burn, or at least only partially. By sampling the centre of a cup-shaped flame produced in a large form of the apparatus, it was found to consist of inflammable gas containing a much higher percentage of methane than the

original coal gas. The hydrogen burned preferentially.

The following result was obtained using a mixture of 50% of pure methane and 50% of pure hydrogen:—

Original mixture		Sample from centre of cup-shaped flame
	%	%
Hydrogen	48.3	10.3
Methane	50.4	36.1
Carbon dioxide	—	0.8
Carbon monoxide	—	0.5
Oxygen	—	2.1
Nitrogen	—	50.2

The observation that increased speed of coal gas stream gives a lower value for oxygen in its extinctive atmosphere may be explained as follows: When the atmosphere supplying the flame contains less than about 15% of oxygen the methane in the gas begins to act as a diluent. In order that it may burn it must absorb heat from the hydrogen flame. Below 15% oxygen, however, the combustible mixture of oxygen and hydrogen is still formed. With slower gas streams hydrogen is burnt too quickly, but by increasing the hydrogen supply, that is by increasing the speed of the gas stream, the combustible mixture of oxygen and hydrogen is produced quickly enough to maintain a flame. The limit to which the increased speed of gas stream can be carried will be reached when the rate of propagation of flame in the mixture is just able to balance the upward movement of the gas.

Preparation of gases.

Methane was prepared by the action of water on a comparatively pure form of aluminium carbide, the gas being washed with ammoniacal cuprous chloride solution to remove acetylene. Hydrogen was removed by passing the gas through a U tube containing oxidised palladium sponge, heated to 100° C. in a water bath. The methane used was analysed by explosion analysis and found to contain 98% of CH₄.

Ethane.—Prepared from zinc ethyl and water. The gas was liquefied by liquid air and fractionated three times, and gave a product with a purity of 98%.

Propane.—Prepared by the action of dilute hydrochloric acid on a paste of zinc dust and propyl iodide. The gas was passed through a cooled worm, and then through concentrated sulphuric acid and strong potash solution; it was then liquefied by solid carbon dioxide and ether, and fractionated four times. The propane had a purity of 99%.

Butane.—Prepared from normal butyl iodide in the same manner as the propane. Purity 99%.

Hydrogen.—Prepared by the action of sulphuric acid on zinc, passed through boiling alkaline potassium permanganate, and then over copper gauze at a red heat, giving a gas of 99% purity.

Carbon monoxide.—Prepared by the action of strong sulphuric acid on a strong solution of formic acid (sp. gr. 1.2); the gas, after passing through strong caustic potash solution, had a purity of 99%.

Cyanogen.—Prepared by heating pure recrystallised mercuric cyanide, the gas being liquefied by carbon dioxide and ether and fractionated several times. It had a purity of 99.5%.

Ethylene.—Prepared by the action of sulphuric acid on alcohol, the gas being washed through water and concentrated caustic potash.

Nitrogen.—This was supplied in cylinders, and was free from oxygen and carbon dioxide.

In conclusion the author wishes to thank Dr. R. V. Wheeler (who suggested the problem as having an important bearing on the composition of coal mine atmospheres) and the Home Office Explosions in Mines Committee for permission to publish the results of the work.

MOISTURE IN RAW RUBBER.

BY G. STAFFORD WHITBY, M.Sc., A.R.C.S.

The amount of moisture absorbed by a sample of Hevea crêpe rubber and by a sample of Hevea sheet rubber (both cut into small pieces) when kept (in desiccators) at 16° and at 30° C. in air of different degrees of humidity, has been determined by van de Leur.* The present paper records observations made† under actual tropical conditions on the variation of the water-content of raw rubber and the relation of this quantity to the humidity of the atmosphere, the form of the rubber, and the presence of serum solids. The observations are confined to rubber produced by acetic acid coagulation from the latex of *Hevea brasiliensis* (the common plantation rubber tree).

The moisture-content of both crêpe rubber and sheet rubber was observed to exhibit a diurnal change, being, on a normal day in the Eastern tropics, very markedly higher in the early morning than in the late afternoon. Three samples of latex crêpe (Nos. 1, 2, and 3), taken at random from a day's crop, showed, after they had become "dry" according to the usual criterion (*i.e.*, the absence of white, opaque spots) and were ready for shipment, the variations of moisture-content recorded in Table I. In this table the temperature and the degree of humidity of the atmosphere at the various times are also recorded. Unless otherwise stated, the samples hung in a small drying shed. Sample No. 4, included in the table, is a sample of sheet rubber and will be referred to later. The samples were of the same size (approx. 30 grms. each), and their thickness was that usual for thin latex crêpe—say 100 grms. per 1000 sq. cm.

The general parallelism between the water-content of the above samples of crêpe and the degree of humidity of the atmosphere is well shown in the following figure. It is also clear from this figure that in general the percentage of moisture present is high in the early morning and low in the late afternoon.

The course of drying of samples of latex crêpe from a time shortly after their preparation to the time when they were dry (*i.e.* free from opaque spots) was followed. It was found that after the percentage of water had fallen to (approximately) 1% the samples showed a negative rate of drying during the most humid part of the 24 hours—say, from sunset to sunrise; and that, in general, the rate of drying was influenced by variations in the degree of humidity of the atmosphere. The figures for the three samples of crêpe quoted in Table I. are given in Table II.

Sheet rubber was found to be less sensitive than crêpe rubber, as regards its moisture-content, to

changes in the degree of humidity of the surrounding atmosphere. It exhibited smaller variations than crêpe in the percentage of water present at different times: on the one hand it retained a higher percentage of water in the middle of a hot, dry day, and on the other hand it absorbed less moisture over-night. Observations on the variations in moisture-content of a considerable number of samples of sheet were made. The figures for the sample of sheet (no. 4, weight 35 grms.) included in Table I. were typical.

It is probable that the higher moisture-retaining capacity of sheet, and, thus, the higher percentage of moisture which sheet samples taken under the usual commercial conditions show, depends upon the fact that the serum solids are removed from the coagulum less completely in the preparation of sheet than in the preparation of crêpe, the coagulum being only rolled and washed in the preparation of sheet, whereas it is masticated in a strong current of water in the preparation of crêpe.

It is to be expected that, owing to differences in the degree of dilution of the latex employed, to differences between different samples of latex in regard to the actual ratio of serum solids to rubber,* and to differences in the amount of rolling to which the coagulum is subjected, commercial samples of sheet will differ somewhat in the amount of serum solids which they contain, and, thus, on the view that the moisture-retaining capacity of raw rubber is associated with its content of serum solids, will vary in the percentage of moisture which they retain under identical conditions. It was, in fact, observed that samples of sheet do exhibit differences in the percentage of moisture which under given conditions they contain.†

The greater readiness with which crêpe, as compared with sheet, increases its water-content in a humid atmosphere may probably be justly regarded as due to the much greater surface which this form presents. As results mentioned later suggest, it would seem that the greater the area of a rubber sample in relation to the weight, the greater is the sensitiveness, as regards water-content, to changes in the humidity of the surrounding atmosphere.

That the presence of serum solids in the dry coagulum is closely associated with the moisture-content of the latter was shown as follows. It

was found that rubber prepared in such a way as to contain the whole or the greater part of the solids of the latex serum had a much higher water-content than ordinary sheet or crêpe and exhibited a greater absolute variation of water-content in response to changes in the degree of humidity of the atmosphere. Table III. shows the percentage of water present at various times in a sample of rubber (in sheet form) containing the whole of the serum solids. A considerable number of other samples of a similar character were examined and found to show variations in water-content of a similar magnitude.

Table IV. shows variations in water-content of three portions of different size from the above sheet, and indicates that the larger the piece in question, the smaller is the extent to which the percentage of water present changes with variations in the humidity. No. 1 represents a portion of the sheet weighing when dry 1.2435 grms.; No. 2 the portion quoted in Table III., weighing 2.5000 grms. In this table are also included for comparison figures for a sample of ordinary sheet (unsmoked; weight, 5 grms.), which are typical of those for four samples of ordinary sheet under observation over the period in question.

Dry samples of the serum solids were prepared and were found to be extremely hygroscopic. Thus 0.315 gm. exposed in an evaporating basin absorbed 36.8% of its weight of moisture within 35 minutes.

Conclusions. The chief conclusions indicated are as follows:—

1. The percentage of moisture in raw rubber in the form of sheet or crêpe varies considerably with the degree of humidity of the surrounding atmosphere. In rubber-producing climates it shows a diurnal variation.

2. Sheet rubber tends to retain a higher percentage of moisture than crêpe.

3. The moisture-retaining capacity of raw rubber is closely associated with the presence of serum solids. The latter are very hygroscopic.

COMPARATIVE METHODS FOR DETERMINING THE STATE OF CURE OF RUBBER.

BY HENRY P. STEVENS.

The state of cure or degree of vulcanisation of rubber may be formulated in reference to (1) the percentage of combined sulphur calculated on the rubber present, that is the coefficient of vulcanisation, (2) the physical properties of the vulcanisate, particularly the load supported per unit cross-sectional area at a given elongation or *vice versa*. The former method is independent of the age and external conditions of the vulcanisate, while the latter is dependent on these conditions. It is therefore necessary to make a careful comparative study of the coefficients and the corresponding physical properties under varying conditions before the latter can be taken as a measure of the condition or state of cure. I have already shown that

* On this point, see O. de Vries, *Archief voor de Rubber-cultuur in Ned. Indië*, Sept., 1917.

† Thus, for example, three samples of sheet (two air-dried, one smoked) hanging alongside one another contained the following percentages of moisture, 9 a.m. (temp. 27.5°): 0.208, 0.217, 0.273.

the physical properties are dependent on the age of the vulcanised specimen,* so that comparable results are only obtainable when the specimens are tested at a fixed period subsequent to vulcanisation. The present results show that the temperature† also has a considerable influence on the physical properties, and uniform conditions must be observed in order to obtain comparable figures.

Three typical specimens of plantation rubber were taken—namely, (1) ordinary pale crêpe, (2) ordinary smoked sheet, (3) unrolled coagulum matured for a few days and then crêped.‡ The same mixing as in previous experiments was used, consisting of 90 parts of rubber and 10 parts of sulphur. Although the results obtained with this mixing are not directly applicable to the mixings employed commercially, it has the advantage of simplicity and the large proportion of sulphur brings about considerable variations in the coefficient and physical properties with relatively small variations in the conditions of vulcanisation. Separate portions of the "mixings" were vulcanised for varying periods, as in the ageing experiments, but with shorter "intervals," viz., 15 minutes in the case of the ordinary crêpe rubber, 13 minutes for the smoked sheet, and 10 minutes for the crêpe from matured coagulum. These intervals were chosen to correspond approximately with the rate of cure of the various rubbers.

The stress-strain curves for a vulcanised rubber may be obtained either directly (by an autographic attachment to the testing machine) or by plotting the values for the loads at the corresponding

ture. The other half of the rings were placed in an insulated box in a cold place, the average temperature being approximately 10° C. which may be regarded as a cold room temperature. Some of the rings were withdrawn from the incubator and insulated box the day following vulcanisation and tested. The others were left in the incubator and insulated box for one week and then tested.

The following tables give the results obtained in the physical tests (loads in grms. per sq. mm. cross-sectional area, corresponding to final lengths of nine and ten times the original length). They also give the coefficient of vulcanisation of each vulcanised specimen calculated from the combined sulphur figure. It is known that the coefficient of vulcanisation is not affected by the age of the specimen, provided that the latter is kept at a temperature not exceeding 60°–70° C.* and that the specimen is not overcured.† This is one of the advantages possessed by the coefficient as an index of the state of cure. The drawback to its use lies chiefly in the laborious nature of the determination and the delay in obtaining results, as the vulcanised rubber is preferably extracted during one whole week to make certain that no appreciable quantity of free sulphur remains in the rubber.

A glance at these figures shows that a difference in temperature of 18° C. produces a marked difference in the results of the physical tests. Taking the crêpe rubber (Table I.), it appears that the temperature has a greater influence on the results than the period of ageing. This is more easily seen if the results be plotted in the form of curves

elongation or stretch of the sample. As these curves are very similar for all vulcanised rubber and sulphur mixings and, when taken for any one sample, do not intersect, their position is most conveniently indicated by the load required to produce a given elongation, or *vice versa*. For the purpose of comparing the stress-strain curves I have taken the loads when the specimens are elongated to 9 and 10 times the original length. Although a fully cured or slightly over-cured rubber may not in all cases stretch to ten times the original length, most of the present specimens stretch to this extent, and they all allow of stretching to nine times the original length.

The method adopted in the present experiments consisted in vulcanising the rubber and cutting rings from the vulcanised product on the same day. Half of these rings were placed in an incubator, where they were maintained at a temperature of 28° C. or thereabouts, that is, a summer tempera-

(Fig. 1). The four upper curves represent the loads corresponding to the coefficients of vulcanisation at a final length of 900% and the lower for one of 1000%. The curves lie in pairs. The individuals of each pair approximate closely to one another, and represent the tests made with samples kept at the same temperature for one and seven days after vulcanising. In the case of the smoked sheet, SS, and crêpe from matured coagulum, MC (Fig. 2), the curves given are the averages of the two ageing periods, and show similar differences due to the difference in temperature between vulcanising and testing. In the case of crêpe from matured coagulum, the curves lie rather more closely than with ordinary crêpe. As an illustration of the considerable effect produced by moderate variations in temperature, we note that the curve for smoked sheet, SS, elongated to nine times the original length and aged at 11° C., cuts the curve for crêpe from matured coagulum, MC, aged at 28° C. (Fig. 2, the dotted line, SS, cuts the continuous line, MC). From this it follows that, over

† This will be shown in a later publication.

a series of vulcanisations, corresponding to coefficients varying from 2 to 3, smoked sheet elongated to nine times its original length will support a load as great as or greater than crêpe from matured coagulum elongated to ten times the original length (no account being taken of temperature variations). Fig. 3 corresponds to Fig. 2 except that the results at different temperatures have been averaged so as to eliminate the effect of temperature. It will be seen that whereas the curves for crêpe, C, and matured coagulum, MC, lie close together, both are some distance from the curve for smoked sheet, SS. Figs. 1 and 2 illustrate particularly the influence of temperature on the ageing factor, while Fig. 3 illustrates the

they run approximately parallel for sheet and ordinary crêpe rubber, but show appreciable variation in the case of crêpe from matured coagulum.

A word may be said with regard to the relationship between the coefficient and time taken to vulcanise the rubber at a constant temperature. Fig. 4 corresponds to Fig. 1 and gives the loads plotted against the time of cure instead of against the coefficients. It will be noted that the curves in the two figures correspond almost exactly. If the coefficient be plotted against the time of cure, as is shown in Fig. 5 (continuous lines) for the ordinary crêpe (C) and smoked sheet (SS), the curves obtained are straight lines or as nearly straight as the limited data and relatively short

differences shown by the three different types of rubber when stretched under varying loads at constant temperatures. It will be noted that the curves for smoked sheet approach most closely to a straight line, while those for crêpe from matured coagulum show the greatest curvature (Fig. 3). This is characteristic of the curves at all ageing periods and temperatures. The curve for smoked sheet at highest loads suddenly takes a horizontal course, but this requires confirmation. These results are not in agreement with statements that have been made as regards the comparative figures for the coefficient and the stress-strain curves. Thus, de Vries and Hellendoorn, who express the curve by means of the length at a load of 1·30 kilos. per sq. mm., state that these figures run exactly parallel to the coefficients.* My results show that

range of vulcanisations can show. In the case of the crêpe from matured coagulum (MC) there appears to be a distinct but slight curvature convex to the abscissa (and not concave, as in the load curves, see dotted lines). This is probably due to the influence of the accelerator, which alters the character of the chemical reaction. The curve marked XX represents the load plotted against the time of cure for ordinary crêpe rubber but when aged at 11° C. and tested the day after vulcanising. Under these conditions the curvature is more marked.

The degree of error introduced by a difference of temperature corresponding to the change from a warm to a cool room, say 18° C., is brought out in Fig. 4. Ordinary crêpe under a load of, say 800 grms., corresponds to a cure of about 180 minutes when the sample is tested at 11·5° C. and 158 minutes at 28° C. If the specimens be kept for a few days before testing, the results are similar.

* This J., 1917, 1258.

Relationship of load and coefft. for ordinary crêpe rubber. Continuous lines give loads when elongated to 10 times the original length. Dotted lines 9 times.

FIG. 2.

Relationship of load and coefft. for smoked sheet (S.S.) and crêpe from matured coagulum (M.C.) elongated to 10 times the original length (continuous lines) and 9 times the original length (dotted lines). All samples 7 days old when tested.

FIG. 3.

Relationship of load and coefft. for ordinary crêpe (C.), smoked sheet (S.S.), and crêpe from matured Coagulum (M.C.) aged 7 days. Average of both temperatures. Continuous lines give load when elongated to 10 times the original length. Dotted lines to 9 times.

FIG. 4.

Relationship of load and time of cure for ordinary crêpe rubber, elongated to 10 times the original length (continuous lines) and 9 times the original length (dotted lines).

How far the figures in the tables are typical of the three types of rubber remains to be seen, but as each of the three samples consists of a mixture of several specimens of raw rubber they should be fairly representative. There are some irregularities in the experimental results, particularly at the higher cures, but the figures as illustrated by the curves in Figs. 1, 3, and 4 leave no doubt as to the trend of the results and illustrate the very considerable variations produced at short ageing periods by moderate fluctuations in temperature. They also show, as was foreshadowed in a previous paper, that the stress-strain curve corresponding to any particular coefficient exhibits appreciable variations between different types of rubber, even when the conditions of vulcanising and testing are the same (Fig. 3). It is probable that a close connection will be found to exist between the curve and the rate of cure when samples are all of the same type, e.g., crêpe containing about the same percentage of caoutchouc. Where the non-caoutchouc ingredients are greater there is an effect similar to that produced by compounding the rubber with foreign ingredients. This will result in a reduced final length corresponding with the capacity to support a greater load at a given elongation. Thus, crêpe rubbers containing more caoutchouc than sheet, should give curves coming lower down on the diagram, which is actually the case as shown in Fig. 3.

Fig. 5 gives both the coefficients and the loads plotted against the time of cure. As in the case

FIG. 5.

Relationship of coefft. (continuous lines) and loads (dotted lines) to time of cure.

of the coefficients, the load curves for ordinary crêpe (C) and smoked sheet (SS) are almost straight lines, but the curve for crêpe from matured coagulum (MC) shows an appreciable curvature but in the reverse direction. It is also interesting to note that whereas the curves for the ordinary crêpe (C) and crêpe from matured coagulum (MC) lie close to one another, those for the smoked sheet (SS) are a considerable distance apart. The reason for this has already been suggested, namely, the larger proportion of non-caoutchouc constituents present in the sheet. The loads supported at a given elongation are all greater in the case of sheet rubber than would be expected from the time of cure and the coefficients. The discrepancy thus introduced is easily calculated. Take the three types of rubber and note the time of cure required for the rubber to support a given load, say 750 grms. per sq. mm. At this point the crêpe from matured coagulum has a coefficient of 2.5. In Fig. 5 (dotted lines) we have MC 60 minutes, SS 51 minutes, C

117 minutes. The rates of cure are therefore as $\frac{60}{2.5} : \frac{51}{2.5} : \frac{117}{2.5} = 100 : 74 : 51$. Now calculate the relative rate of cure of the three samples based on the coefficients (continuous lines, Fig. 5). Take the minutes required to produce a coefficient of, say, 2.5 in the crêpe from matured coagulum which corresponds to a load of 750; the figures are MC 60 mins., SS 109 mins., C 123 mins. The rates of cure are therefore $\frac{60}{2.5} : \frac{109}{2.5} : \frac{123}{2.5} = 100 : 55 : 49$ —an appreciably different relationship from that based on the coefficient. If other points on the stress-strain curve be taken other ratios will be obtained, because the curves for crêpe from matured coagulum diverge appreciably from straight lines.

A few figures may also be given based on the graphs (Fig. 3), showing the differences which may result from the exclusive use of stress-strain curves for the purpose of estimating the state of cure without reference to the type of rubber under examination. Taking, as before, the crêpe from matured coagulum as a standard for comparison, this gives a coefficient of 3 at a load of 1000 grms. At this same load the smoked sheet gives a coefficient of approximately 2.22 and the ordinary crêpe a coefficient of 2.82. That is to say, as judged by the stress-strain curves, the three rubbers are cured to the same degree when, according to the coefficients, the smoked sheet is only 74% vulcanised and the crêpe 94% vulcanised taking the crêpe from matured coagulum as 100% vulcanised. If we take the load at 750 grms., we obtain the corresponding figures 75 and 96 for the sheet and crêpe, which are in fair agreement with the foregoing. At a load of 500 grms., however, the positions of the graphs for C and MC are reversed and the figures become 88 for smoked sheet and 112 for the crêpe, based on MC=100 as before. At higher loads, again, as for instance 1250 grms., the curves for C and MC give smoked sheet 82 and crêpe 100. It will therefore be seen that considerable differences arise when comparing different types of rubber for rate of cure, according to whether the coefficient or stress-strain curves be taken as the basis of the calculation, and this particularly applies to smoked sheet when contrasted with milled, that is ordinary crêpe rubber.

Summary.

(1) The position of the stress-strain curves is appreciably influenced by the period elapsing between vulcanising and testing the rubber and by the temperature. Hence the results are only comparable when these conditions are kept constant. Results obtained in the summer are not comparable with those obtained in winter, nor those obtained in the Tropics with those obtained in Europe.

(2) The position of the stress-strain curves is influenced by the type of the rubber, i.e., whether crêpe or sheet, probably owing to a variation in the proportion of non-caoutchouc ingredients.

(3) The coefficient of vulcanisation is independent of the above and other conditions and is therefore a more reliable index of the rate of cure. In any case, if the stress-strain curves are to be taken as an index of the state of cure, it is essential that these curves be obtained under standard conditions.

(4) Of particular interest is the greater curvature of the graphs for crêpe from matured coagulum than of those for ordinary crêpe and sheet. This may be attributed to the larger proportion of accelerating base contained in the former.

(5) To ensure as great a degree of uniformity as possible, all specimens should be tested as soon as can be after vulcanisation—say the next day—and between vulcanising and testing the specimens should be kept as nearly as possible at say 30° C., a temperature easily maintained either in Europe or the Tropics.

I am indebted to the Rubber Growers' Association for permission to publish these results.

London Section.

Meeting held at Burlington House on June 3rd, 1918.

DR. CHARLES A. KEANE IN THE CHAIR.

THE DETERMINATION OF TIN IN HIGH-GRADE WOLFRAM ORES AND THE USE OF LEAD AS A REDUCING AGENT IN PEARCE'S ASSAY.

BY A. R. POWELL.

The specifications for wolfram used in the manufacture of ferro-tungsten require that the ore shall contain not more than 1% of tin; sometimes the stipulated maximum is lower still, e.g., 0.75%. A rapid and reliable method for determining tin in wolfram concentrate is, therefore, of the greatest importance for the purpose of controlling the work of the electro-magnetic separator and for testing the adaptability of the magnetic separation process to new parcels of tin-wolfram ore, as some varieties of cassiterite show marked magnetic properties.

In the volumetric determination of tin by means of iodine, even a moderate quantity of tungstic acid masks the end-point completely by the intense blue colour of the lower oxides of tungsten formed in the reduction. Hence the necessity for removing the tungstic acid before titration. Several methods to this effect have been proposed and used, but they are, on the whole, too tedious for rapid work, and not always reliable. Of the four methods described below the first three, though slower, were found to give good results, and are useful as a check. The fourth method is rapid and has proved very satisfactory. A preliminary account is also given of the use of lead as a substitute for iron or nickel in the Pearce method.

Determination of tin in wolfram ores. Tin occurs both as cassiterite and stannine in wolfram ores; the former is insoluble in acids and in fused bisulphate, the latter dissolves in *aqua regia*, and fusion with bisulphate renders part of the tin soluble. In case cassiterite alone is present, attack with acids or fusion with bisulphate will dissolve the wolfram and leave the tin oxide unattacked; with stannine, however, the solution must also be examined for tin. In the author's experience cassiterite is quite insoluble in *aqua regia*, but, on fusion with bisulphate, a small amount goes into solution when the melt is extracted with dilute sulphuric acid. This rarely exceeds 1 mgm. and is often negligible.

Method 1. The ordinary *aqua regia* attack of the slimed wolfram ore leaves the cassiterite with the tungstic acid, and, when the latter is dissolved out with ammonia, the small residue left may be fused with sodium peroxide and the tin determined as in the well-known Pearce assay. This is the usual method for removing the wolfram, but its great drawbacks are: (a) the ore must be very finely powdered before attack; (b) the complete solution of the wolfram is a lengthy and tedious operation; (c) the extraction of the tungstic acid with ammonia or soda introduces another filtration; (d) if stannine is present the acid filtrate must be treated with hydrogen sulphide, the precipitate extracted with sodium sulphide to remove copper, and the tin precipitated with acid in the filtrate from the copper sulphide, the washed tin sulphide being ignited with the residue from the ammonia extraction.

Method 2. Fusion of the ore with potassium cyanide was also used, but, though a much more rapid method, it was not free from objections. Thus, when many assays are being conducted at the same time, the fumes from the hot, strong cyanide solutions are apt to be dangerous. Again, the wear on the porcelain crucibles is very great, one crucible rarely surviving more than three fusions. The analysis is conducted as follows: 5 grms. of cyanide is gently fused in a porcelain crucible and allowed to cool again until a crust forms, on to which 1 gm. of ore is gently transferred. The crucible is covered and the temperature raised slowly until vigorous effervescence ceases, after which the contents of the crucible are stirred gently and heated for five minutes longer. After cooling, the melt is extracted with hot water and the insoluble residue, consisting mainly of metallic iron and tin, filtered off, washed free from cyanide with hot water, and dissolved in hydrochloric acid and a little potassium chlorate. The resulting solution is ready for reduction and titration. If the ore contains arsenic, copper, or bismuth, it must be treated with 20 c.c. of nitric acid (sp. gr. 1.2) prior to fusion. The insoluble matter, which contains all the tin, is filtered off, well washed with hot water, ignited, and fused with cyanide. Although the method gave, on the whole, reliable results, inexplicably low figures were obtained at times, so that, while useful as a check, it did not answer well as a control method.

Method 3. The possibility of separating the two metals after getting them into solution as sodium tungstate and stannate was next investigated. Auguat (Z. angew. Chem., 1906, 19, 140) has described a method in which the tungsten is precipitated as blue oxide by means of zinc and hydrochloric acid, but this method was found to be slow and the separation imperfect. As in the separation of molybdenum from tungsten, it appeared possible to separate the tin from a tartaric acid solution of the sodium salts by precipitation with hydrogen sulphide. It also seemed probable that boiling the alkaline solution of the two metals with ammonium nitrate would precipitate the tin as metastannic acid. Both the above procedures were found workable, as the following experiment shows:—0.5 gm. of pure tin oxide was fused with 5 grms. of sodium peroxide in an iron crucible, the cold melt extracted with boiling water, the solution cooled, made up to 500 c.c. and filtered through a dry filter. A number of 20 c.c. trials (=0.0158 gm. Sn) were pipetted into small flasks and treated as follows:—(a) The solution was acidified with hydrochloric acid and reduced direct. (b) The solution was acidified with tartaric acid and saturated with hydrogen sulphide; the precipitate was filtered off, washed, dissolved in hydrochloric acid and reduced. (c) The solution was treated with 5 grms. of ammonium nitrate, boiled till free from ammonia, the precipitate filtered off, washed, dissolved in hydrochloric acid and reduced. (d) The solution was treated as under (c) but the precipitate was ignited and fused with peroxide as in Pearce's assay. The amounts of tin found were (a) 0.0157, (b) 0.0154, (c) 0.0153, (d) 0.0158 gm.

The precipitation with hydrogen sulphide generally gave slightly low results, ascribed to loss of colloidal sulphide in washing. The method as applied to ores is as follows: 2.5 grms. of ore is fused with 10–12 grms. of sodium peroxide in an iron crucible in the usual manner. The cold melt is extracted with water and a little alcohol, the liquid diluted to 250 c.c. in a graduated flask and 200 c.c. filtered through a dry filter. The solution is transferred to a beaker and 5 grms. of tartaric acid added, followed by hydrochloric acid to produce a distinctly acid reaction. The hot solution is saturated with hydrogen sulphide, the

precipitate filtered off and washed with warm 2% sodium acetate saturated with hydrogen sulphide. If arsenic is absent the precipitate is dissolved directly in hydrochloric acid, but, if present, the precipitate is ignited in an iron crucible at a very low temperature and the residue fused with peroxide.

Precipitation with ammonium nitrate is carried out by boiling the alkaline filtrate, obtained as above, with 20 grms. of ammonium nitrate and a little filter pulp until the smell of ammonia is barely perceptible. The precipitate is allowed to settle, filtered off, and well washed with hot 2% ammonium sulphate; it may either be extracted with hydrochloric acid and the filtered solution reduced as usual, or ignited and fused with peroxide. Arsenic, if present, is carried down by the metastannic acid and may cause trouble in the reduction and titration. It should, preferably, be removed by a preliminary digestion of the ore with nitric acid. The methods given under (3) work equally well when the tin is present in the form of stannine as when present as cassiterite.

4. *Author's method.* After removal of the wolfram by fusion of the ore with bisulphate, as usually carried out, the melt is heated with dilute sulphuric acid, which dissolves iron, manganese, and titanium sulphates but precipitates the tungstic acid in a white flocculent form which is difficult to filter and wash free from iron salts. Consequently, on leaching the residue with ammonia, ferric hydroxide is formed, which retains tungstic acid, and re-precipitation is impracticable when time is an important factor. Caustic soda readily dissolves tungstic acid; it also precipitates iron, but in the presence of sufficient tartaric acid, both metals remain in solution. It was thus found possible to obtain a clean residue in one operation; further work showed that addition of caustic soda was unnecessary, since hot 5% tartaric acid readily dissolved the fused cake without separation of tungstic acid.

The exact details of this method, which has proved its superiority, after nearly three years' continual use, are as follows: 1 gm. of the sample, crushed to pass a 90-mesh sieve, is mixed with 5 grms. of previously fused bisulphate in a capacious silica crucible, and the mixture heated, gently at first, finally to a red heat. The crucible

is cooled by standing it in a shallow basin of cold water (taking care that no water enters the crucible); when nearly cold, it is covered with a watch-glass to avoid loss by the splintering of the melt. The crucible is half filled with hot 5% tartaric acid and gently warmed over a small flame, whereby the melt is readily detached. It is then transferred to a beaker, together with 70–80 c.c. of tartaric acid solution, and the whole boiled until the cake has completely disintegrated and all soluble matter dissolved. Another method of removing the melt from the crucible consists in pouring it on to a cold iron or nickel plate. When cold the mass is boiled with 5% tartaric acid in a beaker and what remains in the crucible rinsed out with the same liquor into the main solution. The insoluble material is filtered off on a Whatman No. 1 or 2 filter, well washed with hot water, ignited wet in an iron crucible, and fused with 2 grms. of sodium peroxide. In washing out the crucible and beaker care should be taken that all the tinstone, which has a great tendency to hang back, is washed out.

It was soon found that some ores give slightly low results by this method, and this was traced to solution of a little tin in the tartaric acid liquor; it may be recovered by a hydrogen sulphide treatment, the tin being precipitated as sulphide and filtered off, together with the insoluble matter. Gentle ignition converts the sulphide to oxide without loss.

Ilmenite, columbite, and monazite, if present, are dissolved by the bisulphate fusion and subsequently dissolve in the tartaric acid liquor. Scheelite dissolves completely and no separation of calcium sulphate occurs. If much copper, bismuth, or molybdenum is present, the ore should first be treated with 20 c.c. of nitric acid (sp. gr. 1.2), the residue filtered off, washed with hot water, ignited wet, and fused with bisulphate. Arsenic is volatilised on igniting the residue from the fusion, but large quantities of mispickel or iron pyrites cause much effervescence and consequent danger of loss during the fusion, so that it is better, in these cases, also, to give the ore a preliminary treatment with nitric acid.

Table 1 gives a comparison of the results obtained by the above methods. After the removal of the wolfram, the stannic chloride solution ob-

* The ore was given a preliminary treatment with nitric acid.

tained either by fusion or solution was reduced in a round flask with three iron nails for 30 minutes after the colour of the ferric chloride had disappeared. The reduced solution was cooled in running water after the addition of a piece of clean marble, the nails removed, washed with air-free water, and the solution titrated with a weak solution of iodine (1 c.c.=0.002 gm. Sn approx.). The iodine was standardised against pure tin, and due allowance made for the amount of iodine consumed by the nails (this correction never amounted to more than 0.3 c.c. of the iodine solution).

The synthetic mixture F was made by sliming together 20 grms. of a pure crystal of wolfram and 1.6 gm. of a pure crystal of tinstone.

Note on the use of lead as a reducing agent in the tin assay.

The objections to the use of iron in the reduction of tin solutions are: (a) the blank; (b) the greenish tint of the reduced solution which tends to obscure the delicate end-point obtained with weak iodine, which is, therefore, sometimes difficult to discern within one drop. Search was therefore made for a reducing agent which would give colourless solutions, and this was found in lead, the separation of the chloride being almost entirely obviated by the addition of common salt to the solution and by increasing the strength of the acid so as to give the most rapid reduction possible. The procedure is as follows: The peroxide melt is leached with hot water into a 250 c.c. round flask, using as small a quantity of water as possible, and the solution made just acid with hydrochloric acid. After diluting to 100 c.c., 20 grms. of common salt, 40 c.c. of strong hydrochloric acid, and 10 grms. of granulated lead are added, a funnel is inserted in the neck of the flask and the solution boiled vigorously for 20 minutes after the disappearance of the ferric chloride colour. A piece of clean marble is then dropped in, the solution cooled in running water, diluted with 50 c.c. of cold, boiled water containing a pinch of sodium bicarbonate and a slight excess of hydrochloric acid, and rapidly titrated with iodine without removing the lead. The end-point appears suddenly and may be accurately ascertained to one drop. A few crystals of lead chloride may separate, but they settle readily and do not in any way obscure the end-reaction. In order to ascertain whether the presence of lead during titration would lead to high results, several of the titrated solutions were gently shaken for half an hour and again titrated. In no case was more than 1 c.c. required, hence it may be assumed that during the original titration which usually took less than a minute owing to the small quantities of tin present, the back-reduction, due to the presence of lead, was equivalent to less than one drop of iodine and, therefore, negligible. With regard to the time of reduction, 20 minutes' vigorous boiling is ample for quantities less than 0.05 gm. of tin; for quantities up to 0.1 gm. 30 minutes' is quite sufficient. A certain amount of time is, of course, consumed in reducing the ferric chloride formed from the iron crucible; this generally occupies between 10 and 20 minutes and varies inversely with the quantity of tin in solution.

To reduce further the time taken in the reduction a preliminary treatment with zinc was tried (*cf.* Hutchin's zinc-nickel reduction, *Bull.* 149 *Inst. Min. Met.*, Feb., 1917; this *J.*, 1917, 293) with excellent results. The best method of effecting this was found to be as follows: The cold peroxide melt is leached with hot water, and hydrochloric acid slowly added until all the ferric hydroxide has dissolved giving a clear solution, excess of acid being avoided.

2–3 grms. of zinc dust is sprinkled into the warm solution which is vigorously agitated for a short time. The iron is almost immediately reduced, while the tin is precipitated as metal. The solution, which should occupy a bulk of about 100 c.c., is treated with 20 grms. of common salt, 34 c.c. of pure hydrochloric acid, and 5 grms. of granulated lead, heated to boiling, boiled ten minutes, a small piece of clean marble dropped in, and the solution cooled, diluted, and titrated as before. During the final boiling the precipitated tin dissolves almost immediately; the boiling with lead ensures that no oxidation occurs.

For comparison, reduction with zinc followed by boiling with iron nails instead of lead was tried, the nails being removed before titration. Good results were obtained and the smaller amount of iron in solution enabled the end-point to be determined very sharply. It was found that small amounts of arsenic did not interfere in the zinc-iron reduction, but the effect with lead has not yet been definitely ascertained.

The following table gives results obtained by the different methods of reduction. All the ores were given a preliminary bisulphate fusion to remove the wolfram and the residual tin oxide was fused with sodium peroxide. The standard was reduced in each case in exactly the same manner as the assay.

DISCUSSION.

Dr. W. R. SCHOELLER said that he had found the bisulphate-tartaric acid method to work splendidly; the fusion and leaching could be carried out in 10–15 minutes. He had not tried lead as a reducing agent in the tin assay, but it was desirable to use a metal which gave a colourless solution. Iron gave a fairly pale solution, but was not always sufficiently pure; the same objection held good for nickel, which was certainly not to be recommended for small quantities of tin on account of the dark green colour of the solution. Antimony, which was also used as a reducing agent, gave no coloured compound, but its purity was often doubtful, besides which the metal obtained by the precipitation process contained tin, derived from the tinned iron used. If it was proved that lead was a good reducing agent for large quantities of tin, its use would become more general, as it was one of the purest metals obtainable in commerce.

Mr. C. E. BARRS asked whether reduction with lead had been tried on solutions containing larger amounts of tin than those mentioned. There might be one drawback to the use of lead, and that was the formation of lead iodide when titrating. Perhaps this could be overcome quite as easily by cooling with ice water as by the use of sodium chloride, provided that the vessels would stand the sudden change of temperature. He thought reduction with iron was much to be preferred to the use of nickel; it was necessary, however, to

see how much iodine was consumed in a blank determination, and if the amount was large he always rejected such iron.

Mr. G. NEVILL HUSTLY said that another metal which could be used for the reduction in Pearce's assay and which gave a colourless solution was aluminium. On quantities of 0.1 gram of tin, reduction with aluminium and with antimony (Kahlbaum's purest) gave the same figures. He agreed that the colour produced with nickel was an objection.

Prof. PIRRIE said that in estimating small quantities of tin by the Pearce method and using both iron and nickel as reducing agents he had obtained erratic results varying with the acidity of the solution. The amount of tin found appeared to diminish with the acidity of the solution. Had the author observed whether the results obtained were to any extent dependent upon the amount of hydrochloric acid present?

Mr. GAMBIE suggested that magnesium might satisfactorily be used for reduction.

Mr. CHAPMAN said that he had obtained very good results with certain batches of nickel, but, as had been mentioned by Mr. BARRIS in regard to iron, it was necessary to test the material used. The last batch of nickel which he had used proved unsatisfactory and he believed this was entirely due to the presence of cobalt.

Mr. POWELL, in reply, said he was at present engaged in trying lead reduction on larger quantities of tin; he had obtained some good results in solutions containing up to 0.25 gram of tin, and he hoped to be able to communicate some of the results later. As to lead chloride separating, the addition of sodium chloride prevented its deposition in any quantity. He thought that aluminium and magnesium would be objectionable as reducing agents on the ground that they would precipitate the metal, which would then have to be dissolved again, without any reducing agent being present, to prevent oxidation. With antimony he always found that he got higher results than with other agents, although the results were "concordant amongst themselves." This point was at present under investigation. His experiments so far seemed to show that, in the case of lead, an excess acidity of the solution had no effect. He usually worked with one-third of the bulk of the solution in hydrochloric acid and never found any difficulty with any variety of ore. Many of them which were sent as wolfram ores had been found to contain only 1 or 2% of wolfram and the rest all sorts of minerals (e.g., ilmenite, tourmaline, columbite, etc.), but it did not make any difference as the liquid phosphate-tartaric acid method cleaned out all objectionable impurities.

Communications.

THE MANUFACTURE OF CHLORAMINE T.

By J. K. H. INGLIS.

Although two years have elapsed since Dakin showed the value of chloramine-T as an antiseptic, no detailed account of the method of manufacture has yet been published. The drug has shown itself of great value in cases of cerebrospinal meningitis, diphtheria, etc., and after a trial of a small specimen which I had made, I was asked to supervise the manufacture of a regular supply for the military camps in New Zealand, it having been found impossible to procure it outside the Dominion.

In Dakin's work the starting point for the preparation was *p*-toluenesulphonic chloride, obtained as a by-product in the manufacture of saccharin. No such material being available in New Zealand, details had to be worked out for the manufacture from toluene itself, and these details form the material for this paper.

Sulphonation.

The sulphonation of toluene with concentrated sulphuric acid leads to the formation of the three possible monosulphonic acids; but the higher the temperature the larger the proportion of the *p*-acid (Ber., 1911, p. 2501), the highest proportion being 70 to 80%. The price of sulphuric acid being relatively high in New Zealand, I found it best to use two parts by weight of sulphuric acid (sp. gr. 1.84) to one part of toluene (approximately equal volumes) and to carry out the sulphonation at the boiling point of toluene, 250°C., of sulphuric acid (1.84) is heated to 110°C. by immersing the reaction flask in a heated paraffin bath, and then 250 c.c. of hot toluene is added, the whole being very vigorously stirred with a glass circulating stirrer. The efficiency of the stirring is very important, as upon it depends the time necessary to complete the sulphonation. This reaction was carried out in a flask fitted with a reflux condenser, and only a small loss of toluene vapour took place, sulphonation being complete in about thirty minutes with very little charring. Under these conditions about 75% of the toluene is converted into the *p*-sulphonic acid, the remainder being a mixture of *o*- and *m*-acids. If this mixture of acids was isolated, converted into dry sodium salts, and treated with phosphorus pentachloride, the *p*-chloride could be obtained; but as the other chlorides would be useless there would be a considerable waste of material. We therefore made use of Lange's discovery (Ger. Pat. 57,391) that if water is added so that the mother liquor consists of only 65% sulphuric acid, then on cooling, the crystals that separate consist only of the *para*-acid which separates almost completely—the mother liquor retaining the *o*- and *m*-isomers in solution. In order to carry this out, 45 c.c. of water is added to the reaction mixture after sulphonation as above and the liquid poured out and cooled. The liquid rapidly crystallises and sets to a crystalline cake, and on filtering over an asbestos mat (as in a Gooch crucible) nearly the whole of the mother liquor can be drained away, leaving a white crystalline mass which proves to contain only small amounts of *o*- and *m*-impurities. The crystals that separate appear to be the monohydrate, $C_7H_7SO_3 \cdot H_2O$, and correspond to about 75% of the toluene taken. Hence about 25% of the toluene is either lost as vapour or is contained in the mother liquor in the form of the *o*- and *m*-acids. This separation by crystallisation is, however, not very sharp, and the mother liquor on standing continually deposits further crops, which, however, are nearly free from the *para*-acid.

The *o*- and *m*-acids being useless to us, experiments were made by Mr. C. L. Carter at my suggestion, to see how completely the toluene could be recovered by the action of superheated steam. It was found that if the liquor were heated to about 170° and then a brisk current of steam at 200° were blown through it the bulk of the toluene was rapidly evolved, the distillate containing at first as much as 20% of toluene. When the percentage fell below 5% the operation was stopped, as further continuance was hardly profitable (cf. Armstrong, J. Chem. Soc., 1881, 45, 148). The total amount thus recovered was about 14%, leaving 11% not accounted for. Part of this is lost by evaporation during mixing and subsequent sulphonation, and a small part is left in the sulphuric acid. Probably most of the remainder is lost by evaporation *in vacuo* during the filtration of the crude acid.

The cake of crude *p*-acid is dissolved in water, slightly more than enough calcium carbonate is added to precipitate the sulphuric acid as calcium sulphate, and the still acid liquid is filtered. It is then nearly neutralised with caustic soda, made distinctly alkaline with sodium carbonate, boiled, and again filtered. It is important to remove the calcium as completely as possible as it may become a troublesome impurity in the later stages. This method gives a solution containing only sodium sulphonate and sodium carbonate, and on acidifying with hydrochloric acid and evaporating to dryness there remains a pure white salt consisting of the required sodium sulphonate with a trace of sodium chloride. The sulphonate is so soluble in water that this seems to be the best method of preparation.

Preparation of the sulphonic chloride.

This can easily be prepared by heating together on the water bath approximately equal weights of the sodium salt (dried at 140° C.) (191 grms.) and phosphorus pentachloride (208.5 grms.). In this case the reaction takes place very rapidly and easily and a large amount of phosphorus oxychloride is obtained. Mr. C. S. Hicks, working in my laboratory, found, however, that the oxychloride salt can be used according to the equation, $2\text{XSO}_3\text{Na} + \text{POCl}_3 = 2\text{XSO}_2\text{Cl} + \text{Na}_2\text{PO}_3 + \text{NaCl}$, and he obtained a 76% yield. Hence if less than half the weight of pentachloride be taken and the mixture be heated some hours on the water-bath under reflux condenser the following reaction takes place:— $3\text{XSO}_3\text{Na} + \text{PCl}_5 = 3\text{XSO}_2\text{Cl} + 2\text{NaCl} + \text{NaPO}_3$. The proportions of salt and pentachloride according to this equation are 573 to 208.5, or 2.74 to 1; but the reaction is very slow towards the end as the mass becomes too solid and the yield is apt to decrease. This trouble might be avoided by using the theoretical proportion of pentachloride and sufficient oxychloride, which should then be recovered unchanged. An experimental trial of this gave 92% yield but the oxychloride was not recoverable. We therefore use 2 parts of sodium salt for each part of pentachloride and the action then completes itself more easily and only small amounts of oxychloride are left over—the reaction being allowed to go on over-night under reflux condenser on a water-bath. The oxychloride is then distilled off *in vacuo* and the residue put into cold water. The sulphonic chloride is the only part insoluble and is separated by filtration: a small amount of oily impurity (*o*- and *m*-sulphonic chlorides) can be pressed out from the solid cake. The yield is nearly quantitative, 96–98%. The solid sulphonic chloride still contains small amounts of *o*- and *m*-impurities, but these are gradually eliminated in the later stages.

Preparation of sulphonamide.

This operation, though quite simple in theory, causes a certain amount of trouble without special apparatus. The alternative methods are treatment with ammonium carbonate on the water-bath and treatment with strong ammonia solution. The latter method, if properly controlled, is decidedly the more satisfactory. If the sulphonic chloride is ground to a fine powder and concentrated ammonia is poured upon it, a violent reaction begins almost at once and the liquid boils. In this way considerable amounts of ammonia are driven off and the action is apt to be incomplete. We had some difficulty in procuring vessels in which the reaction could be conveniently carried out under pressure, and owing to the impossibility of getting special vessels made which would stand the action of a hot mixture of ammonia and ammonium chloride, we used stoneware ginger-beer bottles which had a screw stopper with a rubber

sealing. 100 grms. of sulphonic chloride could be placed in each, 100 c.c. of 0.880 ammonia quickly added and the stopper screwed in firmly. On shaking vigorously the action began, and as soon as the bottle became too hot to hold it was placed in cold water. No mishaps occurred and the yield was excellent, the liquid only requiring filtering and the residue washing with cold water. The mother liquors on evaporation give small amounts of the *m*-amide but very little else besides the ammonium chloride. Under these conditions about half the ammonia taken is actually used and on a large scale the unchanged ammonia could be recovered by boiling the liquors. The yield of *para*-sulphonamide is 94–97%.

Preparation of chloramine-T.

The conditions for the conversion of amide to chloramine were given in detail by Dakin, one mol. of amide being dissolved in 1.2 mols. of sodium hypochlorite of definite concentration and the chloramine then precipitated by the addition of strong brine. At first his actual proportions were used, but it was found to be unnecessary to use brine. If the amide is dissolved in a warm, strongly alkaline solution of sodium hypochlorite of concentration 1.3 to 2.0 N, a large crop of chloramine is formed on cooling and the remainder can easily be obtained on evaporation. It is very important to have a decided excess of caustic soda, and for each mol. of amide we usually take 1.05 to 1.1 mols. of hypochlorite and 1 mol. of sodium hydroxide. The preparation of the hypochlorite is of course straightforward. Owing, however, to the cost of acids in New Zealand and to there being no electrolytic source of chlorine, we found it most convenient and cheapest to use bleaching powder as the starting point. The crude chloramine-T obtained in this way is contaminated with sodium chloride; but even the crude crystals on drying contain 92–95% of chloramine. The substance can be easily purified by recrystallisation from water. If dissolved in twice its weight of hot water, a large proportion can be obtained in the pure form (over 98%) on cooling. The final filtration is apt to be troublesome; the crystals do not pack well on the filter and it is therefore difficult to remove the mother liquor completely. If, however, the cooling is carried out rapidly without stirring a different shape of crystal is obtained which filters much more readily. It is thus possible, working with large quantities, to get a product of over 99% purity.

Utilisation of by-products.

In the sulphonation as described most of the toluene is used, but half the sulphuric acid taken is contained in the mother liquors after removal of the toluene by superheated steam. At first it was hoped that it would be possible to recover the acid in the pure state by distillation and use it over again; but there is always some charring and the impurities remaining make it comparatively useless. It contains 34% of water. In the remaining stages of preparing the sulphonate the by-products are small in quantity and comparatively valueless. Some lime or calcium carbonate is used and converted into sulphate, but the quantity is very small. In the preparation of the sulphonic chloride the by-products are sodium chloride and sodium *ortho*- and *meta*-phosphate. It would probably be worth while to utilise the latter on the large scale but our experiments are incomplete. In the preparation of the sulphonamide the chief by-products are ammonium chloride and excess of ammonia. The former can be easily recovered and the ammonia could be made use of with suitable apparatus.

In the preparation of hypochlorite and of chloramine, the by-products are calcium carbonate—a

nearly pure precipitate—and a liquor consisting of sodium chloride and hydroxide. No doubt use could be made of this liquor but we have made no attempt in this direction. The above results have been obtained under laboratory conditions making some pounds of chloramine per week. Owing to lack of filtering apparatus and other labour-saving devices we have not made experiments on a still larger scale; but our experiments have always been made with a view to their application to large-scale operations and we have every reason to believe that they would not fail in commercial practice.

University of Otago,

Dunedin, N.Z.

A SIMPLE AND RAPID METHOD FOR THE ESTIMATION OF ALCOHOL IN SPIRITUOUS LIQUORS.

BY NAGENDRA CHANDRA NAG, M.A., F.I.C., AND
PANNA LAL, M.Sc.

The method for the estimation of alcohol described below is the result of an investigation to devise a simple method for its estimation with a fair degree of accuracy, avoiding distillation.

The method consists in treating a known quantity of spirituous liquor in a glass tube graduated in tenths of a c.c. (or finer graduation if procurable) with an excess of anhydrous potassium carbonate, adding about 5 to 10% of water in case the percentage of alcohol is above 90. The mixture is then thoroughly shaken and allowed to settle (or preferably centrifuged), when it will separate into a lower layer of solid potassium carbonate, a middle layer of saturated solution of potassium carbonate, and an upper layer of alcohol hydrate corresponding with the formula $4C_2H_5OH.H_2O$, as will appear from the experimental results given below. The aqueous potassium carbonate solution (middle layer) contains 0.00275 vol. of alcohol hydrate per c.c.

The composition of the alcohol hydrate was determined by density determinations by weighing, as well as by the glass hydrometer at 15.6° C. The results for specific gravity were 0.81961 and 0.8200 respectively, corresponding with 91.04 and 93.92% of alcohol by volume. The formula $4C_2H_5OH.H_2O$ assigned to the hydrate requires 94.061% of absolute alcohol by vol., 91.089% by weight. The alcohol hydrate does not leave any solid residue on evaporation, showing that it does not dissolve potassium carbonate. The coefficient of expansion of the alcohol hydrate as determined by a weight thermometer was 0.001076; calculated theoretically by extrapolation from Tralles' Table II. the value 0.001068 was obtained.

The formula obtained for calculating the per-

centage of alcohol as the results of experiment and on theoretical grounds is as follows: Percentage of alcohol = $(V + v \times 0.00275)[1 - 0.001068(t - 15.6)] \times 0.7936 \times 94.06 \div W$, where V = volume of alcohol hydrate directly read off in the graduated tube in c.c., v = volume of the saturated potassium carbonate solution (middle layer), t = temperature observed during the experiment in ° C., W = weight of the sample taken in grms., 0.00275 is the solubility (in c.c.) of the alcohol hydrate per c.c. of the saturated potassium carbonate solution, as actually found by experiment, 0.001068 is the apparent coefficient of expansion of the alcohol hydrate, 0.7936 is the specific gravity of absolute alcohol (15.6°/15.6°; it is assumed that the graduation of the glass apparatus used had been carried out at 15.6° C.), and 94.06 is the percentage by volume of absolute alcohol present in the alcohol hydrate liberated (upper layer). (This corresponds to percentage composition by weight, alcohol 91.089, water 8.911, the corresponding density being 0.819514.)

If the volume of saturated potassium carbonate solution is less than 2 c.c. the correction for the solubility of alcohol hydrate in potassium carbonate solution may be dispensed with as it does not appreciably affect the result.

In order further to verify the formula given above, 5 c.c. of Merck's alcohol (marked "absolute alcohol, sp. gr. 0.795") was mixed with saturated potassium carbonate solution, some solid carbonate also being added. The strength of the alcohol as calculated by our formula was 99.46%; the specific gravity observed by means of a gravity bottle was 0.79536, corresponding to 99.44% by weight of alcohol.

The percentage of alcohol found in a sample of whisky was 39.45 using our method, and 39.47 by distillation (using ice).

Numerous estimations have been made in alcohol solutions and spirituous liquors by this simple method and in many cases the results have been tested and confirmed by hydrometer readings. The results obtained were almost identical by the two methods. The point at which there is some slight disagreement between our experimental figures and those of published tables (Tralles' tables), is where the apparent coefficient of expansion of the alcohol hydrate is 0.001076. This might be urged as additional evidence for the existence of this hydrate.

In conclusion it may be mentioned that the method is quite accurate even though not more than 5 c.c. of the liquor under examination be used. Solids in solution do not affect the result. Loss by evaporation is prevented, as distillation is avoided and readings are taken in closed tubes. Ice is not required even if the temperature be high. This method is equally applicable to methyl alcohol.

Meeting held at the Rooms of the Royal Society of Arts on November 4th, 1918.

DR. CHARLES A. KEANE IN THE CHAIR.

THE ALSACE POTASH DEPOSITS AND THEIR ECONOMIC SIGNIFICANCE IN RELATION TO TERMS OF PEACE.

BY PAUL KESTNER, PRESIDENT OF THE SOCIÉTÉ DE CHIMIE INDUSTRIELLE.

INTRODUCTION.

No greater pleasure could be accorded to me than that of bringing you the cordial greeting of the chemists and manufacturers of France.

In addressing you there is added to the natural satisfaction caused me by the honour of being the interpreter of my French colleagues an impersonal and loftier feeling of joy and pride, which arises from the character of this assembly.

Is not this meeting, which has a certain solemnity due to the circumstances, an outward and visible sign of the Entente Cordiale? Is it not also the manifestation of a community of effort and of aspirations the main principle of which has inspired the action of the British and the French peoples and will inspire their economic policy?

With admirable unanimity they have affirmed their intentions. During four years their friendship has been sealed by the heroism of sacrifice on the battlefields of France and the East. To-day it shines in the splendour of a decisive victory. Without doubt, even before this frightful conflict which is convulsing the world and will surely transform it, the men of science and the manufacturers of the two countries were interested in each other's work and followed each other's researches and discoveries attentively. Henceforth, whilst respecting the free expansion of the genius of either nation, they will unite their experimental activities in a co-operation which the sincerity that springs from a common ideal will consecrate. They will set on record their resolve to contribute by scientific and technical labours to the magnificent and historic work of inaugurating the reign of justice and peace. They will pursue this object with the noble ambition of rendering some effective aid to the building up and development of a happier and better civilisation.

It has been said that science knows no frontiers. This would be true as an absolute proposition, leaving contingencies out of account, and it would have been true if the lust of military autocracy, of conquest, and of the absorption and subjection of other nations had not made of science an instrument of abuse, of despotism, and of violence in the hands of a predatory race. The central empires have unnaturally distorted the spirit and the mission of true science, the mother of progress. Under the name of "Kultur" they have associated it with unbridled barbarism, making it an accomplice of the worst excesses.

A close agreement of conscience, an impulse of sympathy, and a confidence which the brotherhood in arms and reciprocal services will render permanent, have co-ordinated the scientific efforts of England and France.

Far from the war having stopped or weakened scientific life, it has on the contrary stimulated it. The zeal of seekers after truth has been galvanised. The progress of science during these

years of strife and the value of the results obtained are without parallel, above all in the domain of applied chemistry. In the future the prodigious efforts of our chemists and the ceaseless help that they have given on both sides of the Channel to the common defence, to augmenting the strength of the Allies, to the continuity, progress, and intensification of the production of the two countries, will be looked upon as a marvel. Thanks to them, to their zeal and their ingenuity, the chemistry of the allied countries which has powerfully contributed to the winning of the war, will, after peace is declared, spread abroad its benefits in all branches of industry.

THE POTASH DEPOSITS OF ALSACE.

I have chosen this as the subject of my address not only because I am a native of Mulhouse and the subject is accordingly of particular interest to me, but also because no other subject is of more interest and importance at the present time.

It is in fact these deposits which form the principal reason for Germany's desperate resolve to keep Alsace-Lorraine at all cost. There are also evidently sentimental reasons for this resolve. Alsace, as has been said, is the symbol of German unity built up on our defeat, and this is the truth.

But for Germany sentiment is only an outward show; it is only self-interest which counts, which directs all the collective activities of the nation. Germany is a business house, whose Emperor prided himself on being the commercial traveller. In this war which they declared on us, the Germans saw merely a gigantic commercial operation, of which the end would justify the means, and which was destined to enrich the firm and ruin their competitors.

The potash deposits of Alsace form the principal reason for Germany's desperate struggle to keep Alsace-Lorraine at all cost. The stake that Alsace-Lorraine represents for Germany, from the economic point of view, is a formidable one: Alsace-Lorraine, outwardly the symbol of German unity, is in reality the key to the industrial and economic supremacy of Germany.

Alsace-Lorraine holds two treasures, the loss of which would be, for our enemies, the downfall of all their dreams of economic hegemony. First it contains the iron-ore deposit of Lorraine, the loss of which would render Germany dependent on foreign countries for over 80% of her iron-ore consumption of 39 million tons. Through her victory in 1871, she gained possession of these huge deposits upon which great blast furnaces have since been erected. The output of iron ore in Germany before the war was 28 million metric tons, of which Germany proper only furnished 7 million metric tons; the remaining 21 million tons were taken from the mines of annexed Lorraine.

The acquisition of the ore-field of Briey, which continues the deposit across the frontier of 1871—an acquisition which was to be the consequence of our anticipated defeat—would have assured to Germany the whole extent of the ore-field, with an addition of a further 20 million tons or more per annum. With this realisation the French iron industry would have been ruined at the same time and would have become tributary to the victor.

What the loss of these ore-fields will mean for our enemies has been clearly pointed out by our President, Prof. Louis, in a paper entitled "La Guerre pour le Minéral de Fer" (this J., 1918, 323 R), in which he shows the importance of the Lorraine ore to Germany, and makes it clear that the object of Germany in making the war was to seize the whole basin of Briey and Longwy, and so to obtain practically the monopoly of iron ore in Europe.

The following passage occurs in a confidential memorandum addressed to the Chancellor, Herr von Bethmann Hollweg, on the 20th May, 1915, by six great German industrial and agricultural undertakings, concerning peace terms:—"The war is in fact only a struggle for the possession of the iron ores in the Lorraine and Longwy districts. Without the ore from Lorraine the war would be lost."

Unquestionably from the standpoint of metallurgy (and one knows what influence this has on German opinion) the object and perhaps the cause of the war was the seizure of the ore district of Briey and of the Belgian and French coal-fields.

This is clearly set out in the document mentioned above, and has since been repeated by the most important people in the German industrial world. They insist upon the annexation of these iron and coal mines, as well as on the dispossession of their tenants.

In restoring to France the iron mines of Lorraine, the Allies have the opportunity of reducing Germany to impotence. Her aggressive force is destroyed, and peace is guaranteed for the whole world.

Let us turn to the question of potash. When she annexed Alsace, Germany, who already had a monopoly of potash, did not know of these Alsace deposits. Fate willed it that they should be in a territory that had become German—deposits which alone would suffice for the world's consumption, and which furnish salts of a richness unknown in Germany. While she possesses Alsace, Germany retains this monopoly, and believes, with reason, that its loss would be for her an irreparable disaster. Germany will never give up Alsace until we are able to dictate our terms to her.

The Société de Chimie Industrielle of France has decided to publish an important work on the potash industry and the Mulhouse deposits by M. Camille Binder, of Mulhouse. It will be a new edition of a work published by the Mulhouse Société Industrielle before the war, but revised and enlarged. This work, from which I have taken some of my facts, will appear, I hope, before the end of this year.

It is not my intention to enlarge here upon the necessity of potash as a fertiliser. There are, however, some figures which it is important that we should realise. The following table gives, from official statistics, the relative production in France and in Germany of the principal crops, as well as the yield of each per hectare. I have not been able to obtain the comparative figures for the United Kingdom.

TABLE I.

Crop.	Country	Area under cultivation (hectares)	Total production (in metric tons)	Output per hectare (in metric tons)
Year 1913-1914				
Wheat ...	Germany	1,974,098	4,655,956	2'360
	France	6,542,230	8,843,127	1'352
Rye ...	Germany	6,414,143	12,222,390	1'905
	France	1,201,630	1,238,200	1'105
Oats ...	Germany	4,438,209	9,713,965	2'189
	France	3,979,270	5,182,600	1'302
Barley ...	Germany	1,654,000	3,673,265	2'220
	France	760,205	1,043,760	1'373
Potatoes	Germany	3,412,201	54,121,146	15'862
	France	1,548,070	13,585,965	8'776
Sugar-beet	Germany	535,309	16,946,000	31'780
	France	216,200	6,070,000	28'080

The soils which furnish these crops in Germany are for the most part the ancient sand deserts.

In order to render them the most fertile land in Europe (some Prussian land produces 5 metric tons of sugar per hectare), it has only been necessary to supply them with potash.

The soils which in France yield crops which seem to us so poor, and which nevertheless are much superior to those of former times, judging by statistics, are most favoured by nature; they are capable of producing a classic granary of plenty.

The second table is striking, and gives the explanation of the preceding one:—

TABLE II.

Consumption of potash fertilisers (in metric tons of K₂O) in Germany, United States, England, and France.

Year	Germany	United States	England	France
1910	359,335	244,910	18,258	22,849
1911	422,340	237,442	20,902	26,468
1912	463,383	215,965	23,414	31,691
1913	536,102	231,689	23,410	33,115

In 1912 German lands received 1400 kilos. of potash per square kilometre, English lands 183.9 kilos., French lands 96 kilos., and American lands 128.9 kilos.

During the war, we have not been able to put potash on our fields; our crops have been diminishing. The Germans, on the contrary, have considerably increased their consumption, employing for their own agriculture the amount that they could not sell to the Allies. In the first year of the war their consumption fell to 483,627 tons, in 1915 they used 520,210 tons, in 1916 681,000 tons, and in 1917 more than 800,000 tons. They were thus able to increase their crops and discount the blockade.

I do not mean to assert that potash alone has produced these results, and that the crops are directly proportionate to its use alone. It is known that it is the association of nitrogen, phosphoric acid, and potash, in varying proportions according to the nature of the soils and the crops required, which controls the maximum yield. But if, in this partnership, potash had been omitted, the other factors, nitrogen and phosphoric acid, could not, as is well known, alone have ensured the results obtained.

The Germans foresee that after the war, in consequence of agricultural experience and the results obtained, their consumption of potash will be double what it was in 1913, that is to say, will exceed 1,000,000 tons per annum. The Potash Syndicate, thanks to the propaganda of an organisation which is always being improved, and thanks to the teaching of numerous agricultural schools, has diffused throughout the country enough of the elements of agricultural science to make the extensive use of potash, combined with other chemical manures, understood as a necessity.

Potash is so necessary for obtaining rich crops that one is tempted to maintain that the State would be justified in finding means to compel farmers to use it. One might also maintain that if the State went so far as to furnish potash gratuitously to farmers, it would be rewarded by the enlarged receipts from the taxes, which would put into the coffers of the State sums vastly exceeding the cost of the fertiliser distributed. In Germany, the people, trained to adopt the advice of scientific men and experts, have no need of this stimulant. Having followed the advice given them, it appears that they use every year more of this fertiliser, which gives them such marvellous results.

One may say that before the war Germany alone furnished the whole world with almost the total quantity of potash used. She thus possessed the

most powerful monopoly that any nation ever had, and she endeavoured with zealous care to ensure its continuation.

Dr. O. N. Wilt, late Professor at the Charlottenburg Polytechnic, one of the signatories to the famous manifesto of scientists, published in the early days of the war, wrote:—

"Our enemies will not succeed in destroying our salt, potash, and soda industries—they cannot even disturb them; for Germany is the richest country in the world in its saline minerals and only uses indigenous means for working and transforming them. Our position as sole producer of large quantities of potash compounds gives us over and above this the power of causing grave injury to the agriculture of our enemies, by stopping the export of the salts which are indispensable to them for manurial purposes.

"The re-taking of Alsace, that obsession which has become in France a national monomania, has not failed to engender, in certain minds, the hope of acquiring the deposits of potash which have lately been discovered in the Alsace sub-soil. This covetousness is the result of borings made in the neighbourhood of Belfort, where negative results have shown that the potash layers had been friendly enough to confine their distribution to the political frontier of Germany."

Whenever strangers tried to acquire an interest in German mines, they were prevented. This was notably the case fifteen years ago in connection with an American company which had bought mines at Solstedt. The German Government intervened to annul the sale, and for a short time diplomatic tension ensued between the two countries.

In choosing the title of my paper, I intended to speak only about the Alsace Potash, but it may be more interesting to give this survey a more general character and to glance also at the other sources from which the world's consumption can be supplied.

North German deposits. It was about 1850 that potash was discovered, at a depth of about 260 metres, in the rock-salt mines of Stassfurt. At that time the value of potash salts as a fertiliser was not known, and it was principally the working of the rock-salt which was aimed at. It was only later, when the fertilising value of potash was realised, that it was searched for. Numbers of companies were formed, not only in the neighbourhood of Stassfurt, but gradually over a wide district, which to-day includes the Duchies of Brunswick, Hanover, Mecklenburg, and Thuringia. Potash salts were worked for the first time in 1862. In 1907 thirty-nine companies for their working existed, united into one huge syndicate, the famous Kall Syndikat, which to-day holds practically a potash monopoly. This syndicate has organised a patient and effective campaign of propaganda in order to induce farmers to use this fertiliser. Its efforts were crowned with such success that in 1913 Germany was obtaining annually 11,607,000 tons, of which huge quantity she consumed half herself.

The composition and the richness of the salts from the German mines both vary materially. The richest is sylvinite, mixed chlorides of sodium and potassium, in which the deposits of Northern Germany are decidedly poor; it contains 26.3% of potassium chloride. Next comes kainite, a mixed salt of potassium chloride and magnesium sulphate containing 26.6% of potassium chloride. In addition to these are "hartsalz," a mixture of potassium chloride, sodium chloride, and magnesium sulphate, containing 21.2% of potassium chloride; carnallite, composed of the chlorides of potassium and magnesium containing 15.5% of potassium

chloride; polyhalite, which contains potassium, magnesium, and calcium sulphates.

With rare exceptions, all the salts from the North German basin contain a fairly large proportion of magnesia, and for the most part must be refined before they can be used even in agriculture. The companies which work them own, for this purpose, huge refining factories, which deliver the salts to the trade with a fixed proportion of potassium chloride.

In 1904 the Alsace deposits were discovered, with much richer salts than those of Stassfurt, and these, immediately coming under the control of the syndicate, completed the formidable economic weapon wielded by Germany.

Galician deposits. The deposits of Stassfurt and Alsace are not the only deposits of potash salts. Those of Galicia have been worked for some years. These beds are of small importance and do not seem to be able to provide even for Austria-Hungary alone, since in 1913 that country imported 21,000 tons of potash (K_2O) from Germany.

Spanish deposit. The Spanish deposit, on the contrary, has perhaps great possibilities. At Suria, in Catalonia, potash was discovered shortly before the war, in a district where rock-salt mines were already worked. The potash was found at depths varying from 38 to 55 metres, and at certain points in Cardona there was even an outcrop.

A Franco-Belgian syndicate acquired the prospecting rights and continued the exploration. The discovery was one of capital importance for Spain and the countries of the Entente, who saw in it the possibility of shaking off the German monopoly. The Stassfurt syndicate, realising the danger that threatened them, and supported by the German authorities, used all means in their power to prevent the development of the Catalonia deposit. Their agents obtained concessions and took shares in Spanish companies; they had already obtained concessions in the adjoining Franco-Belgian deposits. The Spanish Government has just taken energetic action; it will compel the concessionaires to work the mine under a penalty of the loss of their rights, and it will grant no more concessions. It has decided to continue the sinking itself in order to define the limits of the basin.

The deposit extends over a considerable area, but is not continuous in the beds, as is the case in Alsace; moreover, it appears that the working is rendered difficult because the beds, instead of being horizontal as in Alsace, are steeply inclined.

The original Franco-Belgian concession of Suria and Cardona now seems to be the most important. It comprises both carnallite and sylvinite; the carnallite ore, which is the more plentiful, contains at least 12% K_2O . This concession includes 12,000 hectares and works 12 shafts, 300 to 850 metres in depth. The area in which the condition of the beds is favourable for working is about ten kilometres in width. A shaft which should yield 1000 tons per day is being sunk, and should be completed by the commencement of 1919. The Sociedad de Industrio y Comercio, which has also obtained a concession, has sunk three shafts near Cardona.

The development of the work so far carried out shows that Suria is the centre of an old lagoon which at the close of the Eocene and the beginning of the Oligocene period covered the North-west of the Province of Barcelona and the East of the Province of Lerida. We have here a very important reserve of potash in an advantageous situation from the point of view of working, which presents a new threat to the supremacy of the German syndicate.

The *United States deposits* are not potash mines but salt lakes situated in the Rocky Mountains in the States of Nebraska, Utah, and California; the Lake of Searles, in California, is worked by the

American Trona Corporation, which is largely in English hands. This company treats the liquors by concentration and crystallisation in its refinery at San Pedro. The reserves are considerable, and it seems that when the extensions now in progress are completed the Trona Corporation will have a daily output of salt equivalent to 100 tons K_2O .

The *Italian deposit* at Erythrea is of a recent lacustrine formation. It is being worked by a company and will have an output for 1918 of 50,000 tons. The reserves are inconsiderable; on the other hand, the deposit is extremely important on account of the richness of the salt, which contains 80% of potassium chloride.

In *Tunis* to the south of Gabes, a salt lake of 15,000 hectares has been worked since 1915, primarily for bromine, though also for potash. The salt is obtained by solar evaporation and crystallisation; it is called *sebkainite* and contains 40% K_2O . In 1917 this deposit yielded 20,000 tons of salt and it is expected that this year it will yield 25,000 tons. The installations in course of completion should increase the production to 100,000 tons per annum. A refinery has been set up for the production of pure potassium chloride.

In *Chile*, in the Province of Tarapaca, in the Lakes Pintados and Bella Vista, deposits of potassium chloride have been found of which the richest contain 36% of chloride. The reserve, estimated at two million tons, has a content of from 3 to 12% of chloride.

There are also deposits in Peru, in Russia, in Morocco, and in the Province of Overijssel in Holland. None of these has been hitherto developed. A deposit is also said to exist in Sicily.

To complete my list there are the natural deposits of potassium nitrate in India and in Chile. In the latter country it is found associated with nitrate of sodium, but the proportion of potash is small. In Brazil a deposit of potassium nitrate has been discovered containing 89% of this salt.

Finally, salt marshes provide us with mother liquors from which potassium chloride can be extracted, notably at Salin-de-Giraud, in the delta of the Rhone. These works have an annual output of 600 tons containing 72% of chloride.

In addition to these deposits of salt and the other saline sources of supply which have just been reviewed, the war has compelled us to make a careful inventory of the other sources of potassium which we possess, and I doubt whether this work has been better done in any country than in Britain. It is not necessary for me to enlarge upon this; the work which Mr. Chance communicated recently to this Society is so complete that there is nothing to add to it. He has told us that before the end of this year the Oldbury Works will be capable of producing all the potash salts necessary for the country in time of war (see this J., 1918, 222 T). Mr. Chance has recognised that although sources of supply, usually wasted and carelessly squandered, which are provided by blast furnaces, cement furnaces, wool washings, etc., will yield a large proportion of the supplies necessary for the country, in practice it will always be difficult to recover the whole of the potash from these sources and recourse to natural salts in addition must always be necessary.

It must be remembered that the needs of agriculture increase every year, and if we take as a basis of comparison what has happened in Germany, it is not rash to conclude that before many years have passed the 23,000 tons of potash (K_2O) that England consumed in 1913 for agriculture may reach 50,000 or perhaps 100,000 tons. The mine can never be replaced except to a comparatively small extent.

The *Alsace potash* beds are situated in the south of the province in the plain, bounded on the south by the Jura, on the west by the Vosges, and on the

east by the Rhine (see map, page 295 T). Recent borings have shown that secondary beds of the same formation are to be found beyond the Rhine. The deposits extend as far as the suburbs of Mulhouse. They consist of two beds, of which the first, the more important of the two, has an average thickness of four metres and occupies an area of about 200 square kilometres. It is found at a depth of about 650 to 1000 metres (see diagram, page 296 T). The upper bed is less important both in area and thickness; it is fairly regularly parallel to the first and is 15 to 25 metres above it. The beds are formed for the most part of pure *sylvinite*. They are situated below a deposit of rock-salt, which attains a thickness of 240 metres. The upper bed has an average content of 35% of potassium chloride and the lower one of 30%. The layers are nearly horizontal, which greatly facilitates the working. They are not subject to infiltration of water.

The total cubic contents of the two beds is about 700,980,000 cubic metres, that is to say, about 1,472,058,000 tons, the average content of the salts being 22% of potash (K_2O). The whole deposit represents therefore more than 300 millions of tons. One may accordingly reckon that it would suffice for the world's consumption for many years.

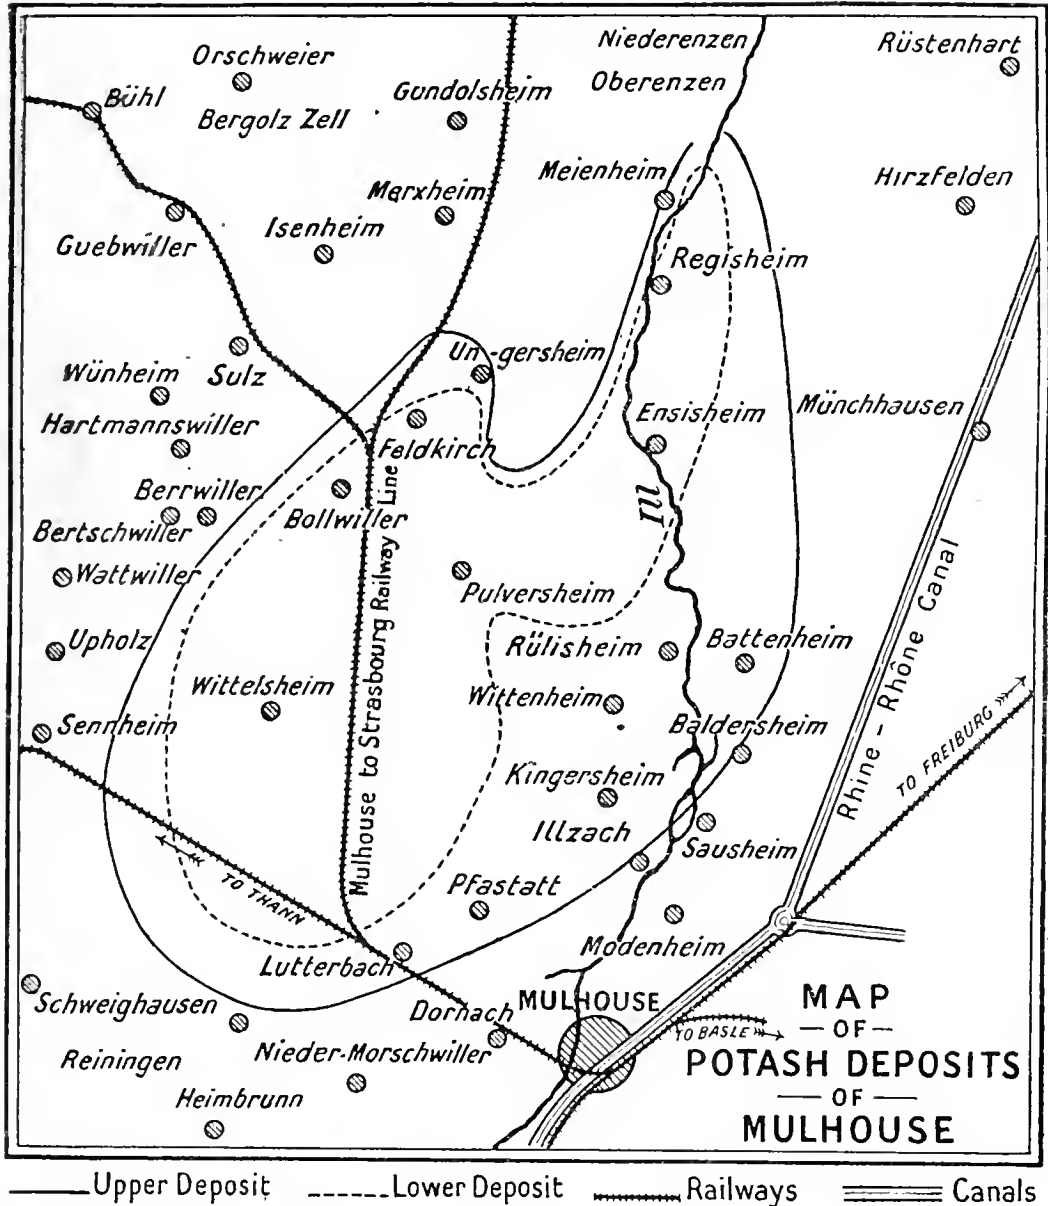

But the most interesting fact is that the purity of the salt greatly surpasses that of all other known deposits of importance, and is notably very superior to that of Stassfurt. Refining is unnecessary for the salt intended for agriculture. The cost of transport is accordingly considerably reduced.

The first boring was made in 1904, near Wittelsheim, by a group of prospectors brought together by the enterprise of Messrs. Joseph Vogt and J. B. Grisez. Their object was to look for coal. At 358 metres, they reached beds of rock-salt; the boring was continued to a depth of 1129 metres; potash-bearing strata were reached without its occurrence being detected. It was only later, in examining samples of a dark red colour, that the presence of potash was recognised. Other borings, decided upon immediately by the prospectors, showed that the deposit was of large extent. The company formed to work this discovery made 165 borings, and began working in their first shaft in 1910. This first company, the *Gewerkschaft Amelie*, has founded affiliated companies in order to profit by the regulations of the German potash cartel, which allows a given output to each centre of extraction working on a concession of 1800 hectares. At the end of the same year, the German company in Stassfurt, the *Deutsche Kaliwerke*, recognising the value of the Alsatian beds and fearing the independent spirit of these new competitors, bought enough shares to secure for themselves the control of the Amelie company. They paid 30,000 marks for shares which had cost their owners 6000. Another group of French and Alsatian capitalists founded the "*Ste. Therèse*" company. This company obtained a certain number of concessions covering 5000 hectares, and afterwards bought most of the shares in two other companies which owned concessions adjacent to their own. The different concessions of the *Ste. Therèse* company have just begun to be worked. Two of the shafts have reached the deposit, and two are now being sunk. Two other German groups have acquired concessions and are carrying out development work. One may therefore say that the potash basin of Upper Alsace is divided among four parent groups or companies.

The German Potash Syndicate has taken care to limit the working of the Alsace deposit, and only allows an output of 5% of the total German output. In order to safeguard the interests of the powerful shareholders of the mines of Northern Germany, the paradoxical situation has been created, that the deposit which furnishes the

richer product and the mines which can be most easily and most economically worked are sacrificed to the poorer. In addition, vexatious regulations were made (which seem, however, to have been annulled shortly before the war) enacting, for instance, that Stassfurt should be taken as the basis from which transport charges were to be calculated whatever the destination might be. Thus, for Switzerland or for France, which are 30 kilometres from Mulhouse, the cost of transport was

represent the State. The President is nominated by the Secretary of State for Home Affairs, and can appeal to the Reichstag. In order to be allowed to sell, a mining company must first join the Syndicate and must conform to its regulations with regard to the organisation of its workings, both underground and surface. The principle of the law of May 25, 1910, which officially established this cartel, is above all to control the sale in order to avoid over-production, and to regulate

as high as for the 600 kilometres, as the crow flies, between their frontiers and Stassfurt. These tariffs were in force even for the countries surrounding the workings.

The Potash Syndicate comprises all the companies which work potash beds in the whole extent of the Empire. Its operations are under Government control. It is managed by a committee of seven, of whom four represent the mines, and the other three, of whom the President is one,

this sale in such a way that Germany shall be favoured at the expense of the foreigner. The State has laid it down as a principle that potash must be considered as a national asset, and must, before everything else, favour the agriculture and industries of Germany. The committee fixes each year the quantities that may be sold by each mine in Germany and the amount that may be exported; it also fixes the selling prices. Factories treating the raw materials cannot be installed, even in

foreign countries, without the authorisation of the syndicate. The syndicate also institutes propaganda for making potash fertilisers better known, and its organisation from this point of view is especially well developed.

A general view of what the situation will be after the war with regard to the world's consumption of potash may be gathered from the following data.

According to the statistics for 1913, and for 1916 where these are available, the consumption was as follows:—

	1913	1916
Germany	536,102	681,000
Austria-Hungary	25,073	—
United States	231,683	—
France	33,115	—
England	23,410	—
Belgium	13,182	—
Italy	6,354	—
Portugal	1,241	—
Holland	43,478 (?)	56,850
Denmark	7,478	—
Russia	24,260	—
Sweden	19,513	23,000
Norway	3,593	—
Switzerland	3,308	6,830
Spain	8,292	—

The world's consumption (calculated as K_2O) for agricultural requirements alone, for the year 1913 amounted to 1,004,000 tons. For the chemical industries it is estimated at 135,000 tons, making a total of 1,139,000 tons.

One may say, generally speaking, that the potash produced by sources other than salt mines, that is to say, from salt marshes, vinasses, kelp, suint, the mother liquor of nitrate of soda, and dust from blast furnaces and cement furnaces, will provide a quantity which almost equals the amount necessary for the chemical industries, so that without committing a grave error, one may admit that the whole of the needs of agriculture must be supplied by the salt mines.

It is interesting to estimate what the needs of the different countries will be after the war and how they can be supplied. It is probable that Germany will supply Austria (except for what is furnished by the mines of Galicia), Russia, Sweden, Norway, and Denmark, to which we may add Holland, although it is to be hoped that Alsace will be able to supply this country by way of the Rhine. Total, according to the 1913 figures, 616,019 tons. Spain will have enough from her own mines and will also supply Portugal. Total, 9533 tons. Italy possesses the mines at Erythrea, and may eventually have the deposit located in Sicily. She will be self-supporting: say 6354 tons. There remain France, England, the United States, Belgium, and Switzerland to be supplied, with a total of 304,704 tons. All these figures are those of 1913, and may be at least doubled for the years after the war. We have already seen that Germany, during the war, has nearly doubled her consumption for agricultural purposes. Certain adjacent countries, such as Switzerland, Holland, and Sweden, have also largely increased their consumption. Deprived of the markets of the countries of the Entente, and with the object of improving her economic position, Germany has made great efforts to use potash as a medium of exchange.

I have already explained that by the loss of the Alsace potash mines, Germany will be deprived of the economic weapon of bargaining, which she thought she could use in order to obtain the imports that are indispensable to her existence when peace is discussed. Without the monopoly

BORE HOLE THROUGH THE POTASH DEPOSITS
AT WITTELSHEIM.

of potash all her system of defence will collapse. Her newspapers, which do not yet admit the possibility of this loss, have continually pointed out the importance of these riches for obtaining favourable economic terms.

The following is an extract from the *Vossische Zeitung* of 23rd November, 1917:—

"The Alsatian potash will multiply the harvests of France. The French are already thinking of the advantages that they will derive from the possession of the Alsatian mines. America comes like the third thief, to show England what an advantage it will be for the Allies if they can get potash independently of Germany.

"America would be able to get larger quantities of potash at lower prices, and we should thus be deprived of the best economic weapon that we possess against her.

"Potash is both wealth and weapon. We shall restrict the delivery to neutrals and to our enemies. If raw materials are refused us, we shall revenge ourselves on enemy agriculture, with this war-cry, At the enemy, with a kilo. of potash!"

In the same paper (26th June, 1917) under the title of "Our Ally Potash," Dr. Roth shows by statistics that the wheat harvests of the United States have been deficient since the shortage of potash. He concludes his article by saying:—

"By a fortunate coincidence, America is not only our principal source of raw materials, but also our greatest buyer of potash. Though the value of our imports from America is much above that of our exports to that country, it must not be forgotten that potash supplies a biological necessity. It is a primordial necessity for the increase of harvest, which nothing can replace and which we must sell at a high price. It is therefore impossible for America to prolong the war indefinitely, unless she consents to see her harvests continually diminishing. If we rejoice at having potash as an ally during the war, we are also justified in the belief that it will swing the balance strongly in our favour when the Peace Treaty is discussed."

In the same newspaper, the next paper, 27th June, 1917, in an article entitled "Alkali and Cotton," Kuhne and Lange bring the same arguments, based on statistics, to bear on the subject of cotton, showing that since the United States had been deprived of potash the crop has sensibly diminished, with the result that prices have been more than doubled. They add:—

"We should treat our potash with the utmost respect, because it is capable, owing to our enemies' lack of it, of producing great fluctuations in securities, or at least of contributing powerfully to this end, without counting its influence on other agricultural products, notably wheat.

"Our experience during the course of the war is that our export of potash to the United States of America (71,000,000 marks in 1913) has an importance far surpassing what had ever been admitted before. It puts into our hands a weapon which our Government will know how to employ usefully when peace negotiations are begun."

Here is another important point. It is known that the German cartel sold at higher prices for export than in Germany, that is to say, that the export trade allowed German agriculture to have its potash cheap. The greater part of this export being suppressed, the syndicate will be obliged to reimburse themselves by raising the prices for home consumption. One may suppose therefore that in the future German agriculture will pay a higher price for potash than foreign agriculture. This is an obvious consequence.

Another point not less important is that amongst all products exported by Germany, potash formed the highest in tonnage. That allowed her to be sure of a return freight in exchange for imports from foreign countries. It has been calculated that potash made up 30% of the tonnage carried by two large German companies. If potash is wiped out as a return freight, since it cannot be replaced

by any other article produced by Germany, the cost of freight for her imports will be considerably increased.

Let us also consider the effect on the yield of the taxes of which the potash mines pay an important quota, and also the effect on the exchange. German economists already estimate at 500 millions of francs the credits that the sale of potash salts in foreign countries will amount to annually for Germany, while she possesses the monopoly of potash.

The *Deutsche Zeitung* of 10th October shows how important the possession of Alsace-Lorraine is considered from the industrial and economic points of view:—

"The German iron industry draws three-quarters of the necessary ore from Alsace-Lorraine. Before the war, the German output of iron ore reached 28 million tons, of which 21 millions came from Lorraine. It must be added that German technical industries have succeeded during recent years in making products of superior quality with Lorraine iron to such good effect that new markets have been opened for her steel industry in the future. The supply of ore is the principal question for the German iron industry, that same industry which, side by side with agriculture, is the foundation of our economic edifice. Hence arises the painful question as to what is to become of the workers in the metal industries and of all the people whose existence is linked up with the iron trade, if the principal district which produces ore is taken away from us for ever. To cede this district would be the downfall of the economic life of our country, it would take away from an important part of the German nation their means of subsistence and either abandon them to misery or force them to emigrate.

"Alsace has another special significance for German economic life. The last years before the war witnessed the development of the Alsace potash industry, which would already have reached its full output had the war not intervened. The Alsace potash beds are amongst the richest that have ever been found. If these deposits passed into the hands of the enemy, it would be the end of the German monopoly of potash. Our enemies would speedily increase the number of companies engaged in this industry, which already amounts to 17, and they would supply the world's market with potash. We need not point out what would follow for our own potash industry and of what a financial weapon the enemy would deprive us.

"Neither do we need to insist upon the way in which these economic facts would react upon the world of workmen, upon the towns, and, in a general way, upon public life in Germany. It is from such considerations that during the last fortnight the total value of the shares in the Wintershall Company, which is interested in the workings of Alsace, has fallen from about 75 million marks to less than 50 million marks."

I have shown by the above considerations that in order to ensure peace for the future, and save the world from German economic dominance, it is indispensable that Alsace should again become French. I have shown that it is not only a question of sentiment and of lofty justice which concerns France alone, but that essential interests which concern all the Allies are linked to this act of justice, and it cannot be too much insisted upon. It is only by the restoration of Alsace-Lorraine that an economic and military victory over Germany can be gained.

Alsace-Lorraine, which was to have been the symbol of German unity built on the defeat of France, will become the symbol of her own defeat. But this is merely sentiment; it will not be enough to stimulate the German soul to revenge. The two

lost treasures, in the eyes of the Germans, will not be Alsace and Lorraine, but the iron mines of Lorraine and the potash mines of Alsace.

DISCUSSION.

Prof. HENRY LOUIS said he felt sure they would all agree that the paper was one of the utmost importance and they were greatly indebted to M. Kestner for having brought it before them. It was important not only on account of the valuable matter it contained but also on account of the psychological moment of its delivery. A week earlier it would have been too early; a week later it might be—he hoped it would be—too late. Let no one say that M. Kestner had touched upon subjects he should not have touched upon, and that the chemist had no right to enter into the domain of politics; this case above all others was the very one on which the chemist ought to speak with no uncertain voice, for this had been above all a chemists' war. It looked like the irony of fate that the First Republic should have sent Lavoisier to his death and that a fresh Republic should have been saved by the efforts of Lavoisier's scientific descendants, among whom M. Kestner could be regarded as one of the foremost. Let them bear in mind that the commencement of this war had been conditioned by advances in chemical industry. The first steps that rendered this war possible were taken forty years ago when chemists applied certain reactions between phosphoric acid and lime to found the basic process of steel-making. The last step that rendered it possible for Germany to enter upon the campaign was taken when other chemists applied the processes for uniting atmospheric nitrogen and oxygen to practical purposes. The first of these steps in industrial chemistry furnished Germany with the steel she needed for her weapons; the last furnished her with the explosives she required for the war. If the war, then, was started in this sense through chemistry, surely chemistry should have a word to say in the ending of it. When Bismarck was settling the peace terms of the Franco-German War of 1871, his first intention was not to have included Lorraine in the German demands. He consulted, however, the head of the Geological Survey of Prussia, who pointed out that iron ore outcrops existed in Lorraine and that it was accordingly advisable to annex it. Bismarck acted on this advice. He (the speaker) feared that we could not claim to have on our side to-day a statesman of the calibre of Bismarck, a man who had the brains at any rate to know his limitations; but surely we might hope that those who were guiding our fortunes had got common sense enough to be guided by his example and to consult technologists who were able to advise them on technical matters in relation to an important subject of this character. He thought M. Kestner had made the prime importance of the Alsace potash deposits very clear and had shown that when these reverted to France—as they would revert to France—the German potash monopoly would be broken for ever. M. Kestner had spoken of the other deposits in various parts of the world. He (Prof. Louis) had worked upon some of them and he believed he was the first to recognise the alunite deposits in the South of Spain, but he was an old miner and he did not trust any deposit, however promising it might be, until pits had been put down and it was possible to know what was actually there. They must not allow themselves to be led away by the fact that because there were promising deposits in Catalonia or elsewhere it was safe to neglect the Alsatian deposits. It might also be relevant to point out that the Spanish deposits lay at steep angles and were much more difficult to work than the flat-lying Alsatian deposits. Furthermore, M. Kestner had not drawn attention—it was outside the strict limits of his

paper—to the petroleum deposits of Alsace. They were not very large certainly, but in a region where there was not much fuel they were important and would add considerably to the mineral wealth of Alsace.

With regard to the iron ores of Lorraine their importance could hardly be over-rated. One point which M. Kestner had not mentioned was that the Lorraine ores were highly phosphoric and the basic slag produced in their smelting had been one of the mainstays of German agriculture. The increase in the output of German agriculture had not been solely due to the use of potash; it had also been due to the large quantities of basic slag obtainable from the Lorraine iron ores. Anybody who followed German technical literature would have seen constant references during the four or five years preceding the war to the iron ore deposits of Briey and Longwy on the French side of the frontier. There had been constant complaints and a bitter outcry from the Germans that France had opened up her iron ore deposits. It had been found that they contained 3 or 4% more iron than the German deposits and bitter complaints had followed that the German ore was being ousted by the French. He had no doubt whatever that the bribe that induced the big German ironworks of Krupp and other works to help in this war—because the war would not have been started if they had not consented—was a promise that they should have the French iron ore deposits as their reward. It was repeatedly stated in the German technical papers that they were going to take the French iron ore deposits so that they would then have a monopoly of iron ore in Europe and be armed for the next war. It was therefore essential for the world's peace that the Lorraine iron ore deposits should not remain in German hands and that France should re-enter into possession of what Germany had pillaged from her. Let them remember that they would leave Germany with ample potash for her own agriculture and leave her with ample supplies of iron ore for the manufacture of ploughshares and looms. But we must take away the iron ore she would use for making guns and submarines. So long as Germany was left in possession of her potash monopoly and of the iron ores she was a source of danger to the peace of the whole world.

Mr. KENNETH CHANCE said there were two points in the paper which especially appealed to him. The first was the complete manner in which M. Kestner had dealt with the potash deposits of the whole world. To have given this information in a paper which was arguing the necessity for Alsace to revert to France was the strongest argument he could possibly have put forward, because in the new world which it was hoped would be developed after this war it was going to be the case of the whole world against Germany until she behaved herself and became worthy of inclusion amongst other nations. The second point was that one could imagine the Germans, who were so famous for their looting propensities, clinging to Alsace because it was about the only thing left which they could not take back to Germany with them.

With regard to the industry in this country, any development at present would only be very small in comparison with the huge figures which M. Kestner had put before them. He did not think, however, that that made it any the less necessary for this development to be carried out to the fullest extent, because although at the present time and for many years to come it was perfectly clear that our friends in France and our other Allies and ourselves would have to work together in every possible way in order to produce what we required for ourselves and for one another, there would come a time when we could each—or those of us who were sufficiently favourably situated—produce

enough for ourselves and have a surplus over. When that time came he hoped we should have developed the potash industry in this country sufficiently to be able to enter into an economic contest with our friends in France to see who could produce potash more cheaply, a contest in which the welfare of humanity was based upon the success of both parties. Although, as he had said, this country's output was very small in comparison with the huge deposits of Alsace, we had one advantage here even though, as M. Kestner had said, the Alsace deposits were richer than those in any other part of the world. From the by-product potash in this country we got a raw material even richer than that of Alsace. It ran from 50 to 60% potassium chloride, which corresponded to about 35 to 40% K_2O . If M. Kestner came before them with the idea that a strong plea was needed to convince them that these deposits should revert to France he must have realised that he was speaking to the converted. There were very few people in England who had not long ago made up their minds that this was bound to come about.

It might be of interest for him to add that caustic potash of the very first quality was now being made by electrolysis from the muriate of potash recovered from blast furnace dust in this country. He had not yet seen a sample, but he understood that the purity was at least as great as if not greater than anything hitherto manufactured by Germany. That was the first development in the British potash industry of this character, and other developments were following on rapidly. The immediate problem, however, was the manufacture on a large scale of the fertiliser, muriate of potash. A full development in this direction would take some years; in the meantime they all hoped that their French friends would supply all the potash required for the needs of this country.

Mr. LAWRENCE WEAVER, of the Board of Agriculture, said that in reference to the figures which M. Kestner had given, the yield of wheat in Germany, translated from metric figures to English measures, was about one ton per acre. The English yield was about 4 quarters. This increase in output in Germany was no doubt, as M. Kestner had said, the result of the enormous amount of potash which the German agriculturist had been able to obtain at a price which, before the war, was about half the price which the English farmer had to pay. Turning to the potato crop, the French yield was roughly $3\frac{1}{2}$ tons to the acre, which struck the English farmer as extraordinarily low. The German yield was about 7 tons to the acre. Last year the average for England and Wales was just under 7 tons per acre, so that without any potash at all we did as well as the Germans. Too much importance must not be attached to the fact that a country like Holland used, on the face of the figures given by M. Kestner, about double the amount of potash that we did. In the first place, some discretion must be used with regard to the English figures. The consumption of potash was given as 23,410 tons for 1913, but it was not known how much of this quantity was used as a fertiliser. Unfortunately, our statistics of fertiliser consumption before the war were extremely deficient. He hoped that things were a little better now; in any case he could promise that when the war was over much more complete statistical information would be available, even to the extent of the use in any particular county of England. It was possible that only about 15,000 tons was used in 1913 for fertilising purposes, and it was probable that for the 1918-19 season we should have used about 2000 tons recovered from flue dust. That was a very trifling quantity, but still it was something, particularly as it was used mostly for the flax crop, which was essential

for aviation purposes. It was quite obvious that we could and should, in the ordinary way, enormously increase our pre-war consumption of potash because the English farmer was now fully alive to its importance. A further consideration was the fact that the land had been so much starved of potash during the last four years. As to whether the increased consumption would be anything like so great per acre as to bring it up to Germany's depended not on the intelligence of the farmer but on the broad lines which agricultural policy was likely to follow in this country. If we were going to increase our arable area very much and maintain the output which was obtained last year our capacity for using potash would be greatly increased, because in order to increase our arable land we should have to take into use light land which in pre-war days was not ploughed. Those who were inclined to blame us for our smaller use of potash compared with Germany should bear in mind that our land was markedly heavier. Germany had a very large area of very light land with which nothing could be done without the use of potash in considerable quantities. Again, the use of potash depended on the crops that we grew. The crops of most importance so far as potash was concerned were potatoes and flax. If we were to build up industries based on our potato crop and use the potatoes for industrial purposes such as the manufacture of spirit and starch we should use a very great deal of potash. If we were going to maintain a large flax area in order to provide aeroplane fabrics we should want potash. Therefore it really depended on what our agricultural policy was going to be, and that in turn depended on what our fiscal policy was going to be. The nation would have to decide what was to be done in that connection. The extent to which the chemical fertiliser trade would flourish would be determined by the character of these developments.

Captain GOONWIN drew attention to potash bearing rocks such as feldspars, glauconite, and leucite as sources of potash, and suggested that in the future one or two processes for the manufacture of potash from potash bearing rocks would play a full share in the solution of the potash problem.

THE CHAIRMAN, in conveying to M. Kestner the sincere thanks of the meeting for his invaluable address, said that in view of its outstanding importance a special effort would be made to distribute it not only to the members of the Society but to as wide a circle as possible, including members of Parliament and of Government Departments, so that the great economic importance of the subject might be brought home to them without delay. Prof. Ostwald, he stated, was reported to have said that it rested with Germany to decide whether in the future the world was to be nourished or starved. M. Kestner had answered this decision; he had added one more nail to the coffin of Germany's arrogant ambitions, and they were sincerely grateful to him for having done so.

They all rejoiced that M. Kestner, the distinguished President of the Société de Chimie Industrielle, had been able to come over to address them. They thanked him both personally and as the representative of his Society for his acceptance of their invitation, and in doing so were mindful of the great honour he had paid not only to the Society but also to all that chemistry stood for in this country and to the nation itself.

The Société de Chimie Industrielle had been founded with aims akin to those of their own Society, and they looked to M. Kestner's visit as a first step towards securing a comradeship in effort for the mutual development of chemical industries as a fitting sequel to the glorious comradeship of French and British in arms.

Sydney Section.

Meeting held on July 17th, 1918.

MR. B. J. SMART IN THE CHAIR.

NITRATION OF POSIDONIA FIBRE.

BY B. J. SMART, B.SC., AND P. PECOVER.

Up to the present time the cultivation of cotton fibre in Australia has not been successful owing to the high cost of labour, and, unless some special means are adopted for the encouragement of the industry, it appears desirable to consider other possible sources of cellulose suitable for the manufacture of guncotton. The attention of the authors was directed to the fact that large quantities of marine fibre (*Posidonia australis*) are readily obtainable at Wood's Point on Spencer's Gulf, South Australia, which it might be possible to purify at a moderate cost so as to render it suitable for nitration. With this object in view the work now described was carried out, and, although only preliminary in character, the results obtained would certainly suggest that further investigation on a large scale would be profitable.

A full account of the distribution and methods of recovery of the fibre is given in Bulletin No. 4 of the South Australian Department of Chemistry (see this J., 1917, 542). It may be stated here that the fibre is best obtained by dredging to a depth of 7 feet from certain flats on the shores of Spencer's Gulf. It is then washed, cleaned, and dusted by means of special machinery, and is marketed in bales. At the present time its principal commercial application has been as a heat insulator, since it has been shown to have a low heat conductivity (Pecover and Smart, Commonwealth Engineer, Dec., 1917, 127). It consists of short, harsh fibres somewhat resembling jute, and usually has a quantity of broken shells associated with it. A sample examined by the Imperial Institute gave 55.9% of cellulose (Reports of the Imperial Institute, No. 58, 1909, p. 133). The fibre as placed on the market contains a large quantity of mineral matter, the percentage of ash in the sample obtained for this work being 16.1. This was, however, considerably reduced by mechanical shaking, the resulting fibre showing an ash content of 11.5%. The ash obtained from the clean fibre was analysed with the following result:—Residue insoluble in 20% HCl, 1.65%; silica (soluble), 2.05; iron and alumina, 12.75; lime, 51.60; magnesia, 9.05; potash, 4.78; chlorine, 6.16; phosphates, 1.81; sulphuric acid, 7.30%; sodium, present.

Purification of the fibre.—The fibre was subjected to a number of processes and determinations of the ash content were made until a value less than 1% was obtained. The methods chosen were purely arbitrary, and it is possible that other methods might be found equally satisfactory. When, however, it was shown that a product practically free from ash could be produced, this product was used for the subsequent nitration.

The following table shows the results obtained:—

Method of treatment	Ash in product, %
1. Treated with nitrating acid and washed ...	6.5
2. Boiled twice with excess of 2% caustic soda ...	3.8
3. Fibre shaken for several hours, four times with water ...	2.8
4. Boiled with (1) 4% sulphuric acid, (2) 1% caustic soda, (3) 1% caustic soda, (4) water ...	0.55

- Boiled with (1) 4% nitric acid, (2) 1% caustic soda, (3) 3% caustic soda, (4) water ... 3.0
- Soaked in 10% hydrochloric acid all night and washed several hours in running water ... 2.12
- Product from (6) soaked again in cold water ... 2.06
- Product from (7) boiled with 5% hydrochloric acid ... 1.1
- Boiled with 3% sulphuric acid for three hours; washed ... 0.68

Nitration of the fibre.—The product from process 9 was considered to be a suitable material for nitration. It was thoroughly dried in a water oven until the weight remained constant, and nitrated for 12 hours in a mixture of 3 parts by weight of sulphuric acid (sp. gr. 1.84) and 1 part of nitric acid (sp. gr. 1.5). The nitric acid was previously prepared to give the required specific gravity by distilling with concentrated sulphuric acid. In order to study any peculiarities attending the nitration of the fibre, other than those which generally accompany the nitration of cotton, a sample of ordinary cotton was nitrated under exactly the same conditions. It was found that greater care had to be exercised in adding the fibre to the acid than was necessary with the nitration of the cotton. The velocity of reaction was greater owing to the fact that a portion of the fibre was in a very finely divided state. The nitrated products were purified by repeated boiling with water. The process of purification took place more rapidly than with nitrated cotton under the same conditions. The finished product gave on analysis 12.3% of nitrogen, and ash content nil. Yield 72%.

Stability.—Heat tests were carried out both on the nitrated fibre and on cotton at 170° F. (76.6° C.), and the following results were obtained:—Nitrated fibre, 10½ minutes; nitrated cotton, 15 minutes; nitrated fibre (after two years' storage), 12 minutes. It was not possible to obtain a higher heat test of the fibre than 10½ minutes, but it appeared probable that this was due to the degree of comminution as shown in Robertson and Smart's work on the Abel heat test (this J., 1910, 130).

Further tests of the stability of the nitrated fibre were made by subjecting it to the Will test at 135° C. For this purpose 2.5 grms. of the purified fibre was heated to 135° C. in a current of carbon dioxide, and the nitrogen evolved measured, with the following results:—

Quarter hours	Temp. of bath, °C.	Vol. of gas, c.c.	Diff., c.c.	Temp. of air, °C.
1	135.0	0.20	0.20	30.0
2	135.2	0.45	0.25	29.0
3	135.0	0.85	0.40	30.0
4	135.1	1.25	0.40	32.0
5	135.0	1.65	0.40	32.0
6	135.0	2.05	0.40	32.0
7	135.1	2.45	0.40	32.0
8	135.0	2.85	0.40	32.0
9	135.0	3.25	0.40	32.0
10	135.2	3.65	0.40	32.0
11	135.1	4.05	0.40	32.0
12	135.0	4.45	0.40	32.0
13	135.0	4.85	0.40	32.0
14	135.2	5.25	0.50	32.0
15	135.0	5.75	0.50	32.0
16	135.0	6.20	0.45	32.0

Air correction per quarter hour, 0.02; total air volume 0.32 c.c.; 2.5 grms. gave 6.4 mgrms. N per 4 hours.

The result showed that the guncotton produced was comparable in stability with Waltham Abbey guncotton, which gives 6.0–6.5 mgrms. in 4 hours.

The values obtained in the above test, namely, "Vol. of gas c.c.," are plotted against the time as shown in the accompanying figure (decomposition curve). The first two values are low, owing to the fact that about 30 minutes is required before equilibrium is established.

Purification of the fibre on a large scale.—In view of the fact that the fibre can be nitrated successfully, it was considered desirable to carry out more extensive experiments on the purification of the crude fibre, in order to ascertain whether the results obtained in the laboratory could be obtained with bulk quantities on a commercial scale. These were carried out by Posidonia Fibres, Ltd., under our direction, and we are indebted to this firm for permission to publish the results.

Process 9 was resorted to in the following work:—An acid boiling vat having a boiling capacity of 150 gallons was constructed of kauri, which was found to resist 3% sulphuric acid. The acid was heated to boiling point by means of steam passing through a lead coil secured to the inside of the vat. The crude fibre, before being subjected to the acid treatment, was loosened in cold water in order to free the material from the loose sand and to save the short fibres which would otherwise be lost if the fibres were merely shaken. After treatment of the first batch with boiling acid solution the fibre was washed by agitation in cold running water, but at the end of 6 hours it was still found to be strongly acid. This method of washing was considered too long and tedious, with the result that boiling water was resorted to and found to be very effective, the acid being completely removed in 2 hours. The purified product was finally dried in the open air on metal trays. The results obtained with various batches of fibre are given below:—

Batch No.	Weight of fibre taken	Time in acid vat	Time in final washing vat	Ash content
	lb.	hours	hours	%
1	50	3	6	0.28
2	50	3	2	1.80
3	50	3	2	0.70
4	50	3	2	1.2
5	50	3	2	1.27
6	50	16	16	1.09
7	50	3	3½	0.73
8	50	3	3	5.4
9	35	3	2	1.28

In batch No. 1 cold water was used for the final washing and found to be unsatisfactory. In batches Nos. 2 to 6 boiling water was used in final washing and found to be quite satisfactory. For batch No. 7 fresh acid solution was put in the acid vat. For batches Nos. 8 and 9 the same acid was used as for No. 7.

The high ash figure obtained with batch No. 8 is probably due to an error on the part of the foreman; it cannot otherwise be accounted for.

Conclusion.—From the work carried out it has been shown that a stable guncotton can be produced from *Posidonia* fibre, and that the fibre can be purified on a commercial scale so as to render it suitable for nitration. In order to investigate the possibility of manufacturing guncotton commercially, plant would be required which we have no means of getting at the present time. Enough has, however, been done to provide *prima facie* evidence of the practicability of using this fibre as a raw material for the manufacture of nitro-cellulose should circumstances demand it, and it certainly would appear to us worth while to carry through one or two nitrations on a large scale to elucidate this more completely. This must, however, be left to those having suitable plant at their disposal.

Annual Meeting, Bristol.

Wednesday, 17th July, 1918.

COPARTNERSHIP.

BY ERNEST WALLS.

(ABSTRACT.)

The story of British industry is the story of a long series of evolutionary changes. With the advent of the steam engine the self-contained craftsman passed away, and modern developments have brought with them their problems and complexities.

Chemical industry came into being long after the disappearance of the craftsman, and it would therefore be a difficult task to rehabilitate the worker in this industry as a self-contained unit. Our present wages system is the empirical result of the application of various wages theories. The "subsistence theory of wages" was unfortunately applied to "industrial" wages in England at the time of the industrial revolution. Later came the "wages fund theory." Under the previous theory if the workers increased their earnings increased population redressed the balance; under the new theory capital performed the same function, for wages could only come from a fixed fund, and if they were increased beyond the limit thus available, capital was depleted and the fund reduced. Then came the fixed time wage, although the theory of supply and demand associated with it disappeared when the Trade Unions developed and collective bargaining began to make its influence felt. Bonus systems, piece rates, and other methods of gain-sharing gradually appeared, and eventually it was realised that the product of industry was a joint product of capital and labour.

Copartnership, however, starts from an entirely different ethical and scientific standpoint. Under this theory production is joint as between capital and labour, but their sole *raison d'être* is service to the third copartner—the community. True copartnership, as distinct from profit-sharing, seeks suitable means of division of the total product of industry, and makes copartners not only profit-sharers but shareholders in the business. An ideal copartnership would be framed on the following lines. The first charges on every industrial under-

taking are a minimum or standard interest on capital and a minimum or standard wage to labour. Capital being further protected and conserved by necessary charges, such as depreciation of plant, against the earnings of the business, it is reasonable that labour should be similarly protected and conserved by equivalent charges, such as a labour reserve for old age and so on. After charges for capital, labour, and their respective reserves have been met, there remains the residuum which, if excessive, is evidence that the consumer has paid too much for the services, and *vice versa*. The consumers' part of the residuum would be returned to the State in such a way as to ensure its ultimate return to the consumers, while the remainder would be divided as between capital and labour on the basis of the profit-sharing capital and the total wages paid.

The initiation of copartnership schemes in England coincided with the Limited Liability Act, although one scheme is recorded in 1829. Copartnership schemes have existed in France during the last 50 years, and a very notable one, dating back to 1880, is that of Godin of Guise. In England 38 gas companies practice copartnership on a model arrangement drawn up by the late Sir George Livesey, who initiated the South Metropolitan Gas Company's scheme in 1889. The division of the profits with the third copartner is, in the case of gas companies, unique.

As far as the South Metropolitan Gas Company's scheme is concerned, 4% dividend on capital and 3s. 1d. per 1000 cubic feet of gas is taken as a basis. For every penny reduction in the price of gas the shareholders receive an additional 2s. 8d. % and the employees receive $\frac{3}{4}$ % (15s.) upon the amount of their annual wages. Thus in 1912 the price of gas was 2s. 2d. per 1000 cubic feet, the shareholders received £5 9s. 4d. % dividend and the employees $8\frac{1}{4}$ % bonus. In this scheme increased efficiency benefits the three copartners, namely, the consumer, the shareholder, and the worker.

It will readily be realised, however, that before the ideal division is obtained, capital will need to be scientifically standardised because of such features as "watered" or written-down capital, and an absolute, as against a relative, meaning assigned to it. Nevertheless, the essential principle is not affected by these difficulties, which are inseparable from the complex character of our modern industrial system.

The method of division adopted by Messrs. Lever Brothers, Ltd., is worthy of notice. Partnership certificates, of purely nominal character and having no exchangeable value, are held by employees and correspond to the share certificates held by the ordinary shareholders. The same dividend is declared both on the ordinary capital (after paying 5% interest) and on the partnership certificates. These partnership certificates are of value only to the owner, but they pass to the widow of the copartner, and upon the death of the survivor they cease to exist. When the copartner is no longer employed by the company his partnership certificates cease to exist, but he is entitled to any accumulated dividends standing to his credit. In the distribution of certificates an attempt is made to distribute the award in accordance with individual merit. In the first place the certificates are based upon a percentage of the previous year's earnings. Secondly, the individual employees are assigned to several classes dependent upon the individual merit of each worker, and in accordance with this grading the percentage on wages may be above or below the average allotment. Appeals from copartners can be made to democratic committees. There is a maximum holding of partnership certificates. As it is impossible to assign to each labour unit its due

share in achieving any realised surplus, the copartners, as in the majority of other schemes, share collectively, but in the case of partnership certificates individual merit is enabled to be appraised and receive its due reward.

As to the form of distribution, almost all the pioneers of copartnership realised that one essential of true copartnership was that of the encouragement of thrift. It is seen in the evolution of the modern industrial system from the old craftsman system that labour and capital in the same individual became necessarily separated. The means whereby the worker may be re-created as the owner of the means of production has been constantly sought by economists and reformers, especially by Mill and Mazzini, and copartnership aims at making every copartner a joint owner of the means of production. Before the war it was calculated that the average capital required per worker in British industry was £200, and this amount invested in the business in which he is a copartner has for the worker under present day conditions a productivity far more than the equivalent of the old craftsman's workshop with £200 worth of tools; there are to-day something like 200,000 copartners in this position. Thus a linking of capital and labour in the sharing of capital as well as in the earnings is the aim of every copartnership.

To encourage thrift the gas company method is to place half the bonus to which the copartner is entitled yearly to a deposit or savings account at 3% interest, and the other half is placed to a trust account for investment in the company's stock. Although all the bonus is the absolute property of the copartner, he must not sell or pledge his stock nor withdraw from his deposit account except under special circumstances. In the author's opinion this seems to restrict individual freedom and thereby to lead to suspicion.

In the case of J. T. and J. Taylor, Ltd., of Yorkshire, surplus profit over 5% is divided at the same percentage rate between capital and labour, and copartnership earnings must be allowed to accumulate in the form of shares by each employee until a sum equal to one year's wages or salary is reached, after which copartnership earnings may be withdrawn.

By the Lever Brothers' Copartnership Trust, founded in 1909, absolute freedom is given to the copartner as to the disposal of his copartnership earnings, but there is a strong incentive in the scheme to induce the copartner to retain them as shares. The dividend on the partnership certificates is distributed in the form of 5s. shares in the business, which form a special block of 5% cumulative preferred ordinary shares, and these a copartner can sell back to the company at par. With the ordinary public these shares carry 5% cumulative dividend, but an active copartner receives an extra bonus, making the total dividend on the shares equal to the ordinary dividend for the year. It is therefore conceivable that under a copartnership scheme based upon such a plan by the effluxion of time, capital held by the copartners will take the whole of the surplus, as has happened in the French scheme of Godin. Shares remain, in Lever Brothers' scheme, the absolute property of the copartner, but on death revert to 5% interest-bearing shares. Those therefore who become shareholders do so by conviction rather than by the less gentle method of conscription adopted by gas companies.

Provision for sickness and old age should be a reserve and a charge prior to the ascertainment of profits, although in many existing copartnership schemes the withdrawal limitation practically makes them into a special form of sickness and old age fund. The copartner should be free to make use of the opportunities copartnership affords him,

but if there are shackles on the opportunity, it is no true copartnership.

In the Godin scheme, dating back to 1880, and in the business of which the members have now become the sole owners, the surplus profit after payment of all fixed charges and 5% on capital, is divided, 75% to capital and labour, and 25% to management. The division of the 75% between capital and labour is based in the case of labour on the total wages paid, and in the case of capital on the fixed interest received by capital. An ingenious method also exists of grading the workers according to ability. Dividends are paid to the workers in the form of savings certificates which receive the same interest as the shares, and on retiring each member receives cash for his certificates, thus carrying with him the cash representing his lifetime's savings. Among other features of the scheme is a community housing scheme. Godin's summing up of copartnership is expressed in his words: "To each according to his capacity, to each capacity according to the service rendered."

The Works Committees advocated in the Whitley Reports are virtually a creation of copartnership, as the management of the trust funds has invariably led to the establishment of a democratic council. In the cases of the South Metropolitan Gas Company and the South Suburban Gas Company this principle has been further extended by the election of three directors of the company by the employee-copartners themselves. Copartnership in profits, however, precedes copartnership in control, and progress can only be gradual.

Properly speaking there are three agents of production, namely, labour, management, and capital, but true copartnership includes both controlling management and controlled labour, and this incidentally solves the difficult problem of remuneration to management. In Godin's scheme management consists of a council selected from the employees with a supreme controller, and such council takes 25% of the surplus.

The interdependence of the units of production is better understood in a copartnership business, and the important part played by management and the possibilities that await enlightened labour respectively are mutually realised. "Copartnership is comradeship, brotherhood in business," said Sir George Livesey. Advancement depends of course on individual effort and determination, and the regular distribution of copartnership earnings in conjunction with a grading plan ensures a continual review of all workers.

The author puts forward copartnership as a positive scheme based upon the existing industrial structure. While in no sense a panacea, it is a scientific attempt at an equitable distribution of the proceeds of industry, and as such, copartnership schemes are successful and fruitful. Failures have almost entirely been failures of false copartnerships. The possibilities are immense, and are no less remarkable from the point of view of productivity, which must inevitably and voluntarily increase. With the passing of years the copartners' savings are accumulated, and a right understanding of copartnership is therefore only a question of time, although some suspicion of a hidden motive must naturally be encountered. Finally, what copartnership needs most of all is an accession of strength, and a source of this might well be found in the chemical industry.

DISCUSSION

Dr. CHARLES CARPENTER said that the chemical industry would reap none of the benefits from copartnership after the war unless labour took up an attitude different from that which actuated it to-

day. When Sir George Livesey twenty-nine years ago had been able to put into effect the ideas that had been in his mind for many years, he had described the condition of affairs which then existed as one in which the worker endeavoured to do as little as he possibly could and get as much as he possibly could for it. That appeared to express to a large extent the attitude to-day. But whilst they wanted the highest possible results from the point of view of chemical reactions and also from the point of view of the workmen whom they employed, they did nothing to instruct or educate the average worker. The result was that after he left school it was only the socialist agitator who took any trouble to instruct him as to the real basis of industry. Copartnership educated the worker into a knowledge of the principles upon which industry should be conducted, and having educated the worker on those principles they found that he was not very different from other people. Another aspect of copartnership, which was a most important one, was that it gave the worker an opportunity of providing for old age, and of being independent of those clubs and organisations to which most of the workpeople had been driven. In that respect there was something to be said in favour of what had been described as the Gas Company's system, according to which a man was given his bonus in the form of ordinary stock of the Company. If he died it became his wife's property and it was handed on to his children. It was his property in the real sense of the word and was as inalienable as property should be. In building up systems of copartnership one of the initial difficulties was that as soon as a worker who had never been accustomed to anything but his wages got something in the way of a bonus, he almost invariably spent it very quickly. A great many of the schemes had come to grief because instead of the money being properly used it was wasted, and instead of the workman being better off for it he was worse off. Therefore there was an advantage and not a disadvantage in making it inconvenient for the worker to get rid of his stock as long as he continued in the particular employment of which he was a profit-sharer or copartner. The original idea had been that one half of the bonus should be invested in permanent stock and the other half invested so that the investor could, if necessary, draw upon that fund for temporary assistance.

As regarded the effect of the system on labour, there had been opportunities of making a direct comparison between labour output with and without copartnership, paying the same rate of wages and using identical machinery, and it had been found that there was a great advantage to the credit of copartnership workers. The gas companies were not in a happy position at the present time. Copartnership, or profit-sharing, existed still with them, but there was no profit to divide and the workmen were getting no bonus and only the ordinary wage applicable to the industry. The copartners had approached their committee and after discussing the question of the 12½% award, they had decided that the conditions of the company did not warrant their pressing for the award. That was a very remarkable example of how working men trained in copartnership would look at the question from both sides. Another point was the much debated one on the value of having working men on the board of management. The men themselves would be the first to say that the great bulk of business carried on round the board table was quite beyond them, but there were many matters appertaining to the conditions of employment and work generally where the advice and counsel of the men were extremely valuable. There was also the advantage that the working men knew that they

were directly represented on the managing body. After an experience of many years he would be sorry to depart from the principles practised by the South Metropolitan Gas Co. The future of industry, and the chemical industry no less than any other, depended on how labour could be educated to take its share in the management, and if they took the same pains in getting the maximum yield from humanity as from brains, he was sure they would get as valuable a result from it. The South Metropolitan Gas Company had a coupling-out committee of the workmen which had dealt with 2000 cases, quite apart from the authorities, as to whether men were or were not indispensable, and in that way hundreds of men had been released for the army who would otherwise have been going on as usual. At the time of the Boer War, when the allowances to the dependants of soldiers who had been killed or who had died in the war were very small, the copartners took upon themselves the problem of making allowances to the widows and dependent children, so that the latter could be brought up until they reached the age of 16. It was only about the time that the present war broke out that the last of these responsibilities ceased. They had done precisely the same thing in the present case, and many hundreds of cases were being dealt with through committees individually.

Mr. W. D. A. Bost expressed the opinion that profit-sharing ought to be applied to the whole country, although difficulties would be encountered with the small employer having limited capital to whom a return of 5% would not be adequate. It would be necessary to fix a minimum wage before any profit-sharing scheme was devised. With regard to the excess profits tax, he thought that the most rational means for obtaining the objects in view of producing at the cheapest price and competing on the best terms would be to continue that excess profits tax and divide the money so obtained among the workmen either according to trades or uniformly throughout the country. That would be an inducement to the workmen to give maximum output. But the first thing was to arrive at an adequate minimum wage for the lowest paid workmen.

The PRESIDENT, in closing the discussion, said that industry in this country could not survive unless we succeeded in persuading the workers that their interests lay not in producing as little as possible, but as much as possible. Until that economic fact was brought home to the workmen of the country our task would be a difficult one. One drawback to copartnership was that it did not directly reward productiveness. His own view was that some modification was necessary by which the workman was paid in proportion to his production. It was not easy to do this but he did not regard the problem as insoluble. Again he somewhat disagreed with Mr. Walls' view that management should be merged in labour. He thought the copartnership idea would have to be extended to include three partners, *viz.* capital, labour, and administration—by which he meant administration in the very widest sense possible—each of which deserved an adequate reward. There was a great deal in Dr. Carpenter's view that it was distinctly injurious to the working man, certainly until he was better educated economically than he was to-day, to trust him with large sums in the way of bonuses, because the money was often squandered. The manager of one of the largest coal and iron concerns in the country had said that the three years' drink bill of the workmen of that company was equal to the capital of the entire company. With facts like these, one was impressed with the danger of entrusting the workman as he was to-day with lump sums of money.

Mr. W. D. A. Bost writes as follows:—All the examples given by Mr. Walls are actual or virtual monopolies who can raise prices at will to cover any bonuses given, so that those who have actually put money into them will not be losers, and it is the public therefore who pay these bonuses. There is one exception, *i.e.*, Godin, and in this the original shareholders were forcibly paid out. If one or a few firms in any trade give special terms and inducements to their men, they will secure the best men and those who will work so as to secure the benefits aimed at, but if every firm in that trade were to do the same they would all revert to the *status quo ante* unless the terms were such as to obviate this. It is our duty to ascertain whether such terms can be made as would attain this end, and whether they would be immediately acceptable to the men and those who have sunk their money or propose putting money into any business. Any scheme must be such as to induce the investment of capital in home industries. The effect of it must be such as to cheapen production compared with the rest of the world, so that we may sell the extra production and also increase the purchasing power of the wages, thus avoiding the necessity for giving higher wages. Any scheme based on a return on the capital invested would fail, as either small capitalists putting their money into a business to be worked by themselves could get out of it by allowing themselves big salaries, or they would be prevented from starting for themselves. It would also tax industry while leaving the professions and commerce untaxed. Profits arise from capital, management, and cost of production, and no workman (in its accepted sense) could be entitled to share in any but the latter category except under special circumstances. Also if bonuses dependent on profits were paid on the profits of individual firms, the men would be underpaid in one works and overpaid in another, though each might have given equal service. These are a few of the difficulties in the way of a comprehensive, equitable scheme, but I venture to suggest the following crude idea: I divide wages into two portions, *i.e.*, a basis wage variable according to the index number or in any other fair way, and a capital wage being, as it were, interest on time spent in acquiring a trade. I then take the ground that any profit owners may make greater than before the war is due to sacrifices made by all in winning the war and securing our freedom of action. A further profit may be made by cheapening production. If by either or both of these conditions greater profits are made, a part of them should come back to those who have made them possible. If, on the other hand, no extra profit is made they have no right to them. If a greater output is required per man per machine, the machines must be kept capable of turning out the greater output, and far greater allowances for this purpose must not only be made before taxation steps in but be enforceable before profits are divided. There would be probably other safeguards necessary, but if, after the basis wage is paid to unskilled labour and basis plus capital (the addition of these being the same amount as before the war), there should remain a profit greater than before the war over the total number of firms in any particular trade, this should be divided in certain proportions between the owner and the workman, the workman getting a part (spread over the ensuing year) as additional wages but the greater part retained for disbursement later on as old age pensions or provision for incapacity to work through accident or disease. This extra profit would be collected as a tax by Government and the amounts disbursed by firms in extra wages the following year reimbursed to these firms by Government out of the funds at their disposal.

Communications.

AGEING OF VULCANISED PLANTATION RUBBER.

PART 1.

BY HENRY P. STEVENS.

In a previous communication¹ there were recorded the results of a series of experiments on crêpe and sheet rubbers in which the vulcanised specimens were re-tested physically at intervals of a few months. It was shown that, in those cases in which the coefficient of vulcanisation exceeded the figure 3.2, deterioration set in a short time after vulcanisation, and that the higher the coefficient the more rapid the deterioration.

It was thought desirable to extend these experiments, and a fresh series was begun with a view to carrying out ageing tests over a longer period and to include a wider range of types, among them rubber from matured coagulum (slab). These experiments are now complete as regards ordinary pale rolled sheet and unrolled sheet (slab). Mixings

ordinary fluctuations of room temperature. When comparing the results it must not be forgotten that determinations of breaking strain are subject to appreciable experimental error when the rubber is overcured and brittle or "perished."

In a recent communication² it was shown that at summer temperatures the effect of ageing on the physical properties is much greater than at winter temperatures. Consequently the effect of ageing on the physical properties, as brought out in these tests, will be more evident in summer than in winter, and the recorded figures will not be directly related to the period of ageing.

The coefficient of vulcanisation was also determined shortly after vulcanisation and again at the conclusion of the ageing period. The results were as follows:—

Hours vulcanised	(1) Rolled sheet		(2) Unrolled sheet (slab)	
	Beginning of ageing period	End of ageing period	Beginning of ageing period	End of ageing period
2	2'33	2'16	3'16	3'44
2½	2'62	2'72	4'17	4'30
3	3'05	3'33	4'93	5'11
3½	3'98	3'90	5'71	5'81
4	4'36	4'62	6'41	6'88
4½	4'73	4'96	7'01	—

FIG. 1 A. Ordinary Sheet.
Breaking Strain

FIG. 2 A. Unrolled Sheet
Breaking Strain

of 90 parts of rubber and 10 parts of sulphur were cured at 35 lb. steam pressure for 2, 2½, 3, 3½, 4, and 4½ hours, and the vulcanised specimens were tested one week after vulcanising and subsequently at intervals extending over 120 weeks. The specimens were preserved in the dark, or in semi-darkness, but otherwise no particular care was taken with them, and they were exposed to the

These figures indicate that with coefficients of over 3 there is a tendency for the coefficient to increase with the ageing of the specimen, the effect being greater the higher the coefficient. It is probable that this increase is accompanied by decomposition of the rubber. It is well known that sulphuric acid is formed when rubber perishes. It appears, however, that where the coefficient is

¹ This J., 1916, 872.

² This J., 1918, 281 T.

low appreciable deterioration does not set in during the period under test, and little or no increase takes place in the coefficient.

The curves plotted for the breaking strain (figs. 1A and 2A) first rise and then fall again when the coefficient does not exceed about 5 units. With higher coefficients the curves fall from the start. Taking (1A), the graphs for ordinary pale sheet, an increase in the breaking strain takes place with ageing at all cures. The higher the coefficient the shorter the period of increase in breaking strain. The figures are approximately as follows:—

(1) Ordinary rolled sheet		(2) Unrolled sheet (slab)	
Coefficient	Period during which increase of breaking strain takes place	Coefficient	Period during which increase of breaking strain takes place
2.3	35 weeks	3.2	21 weeks
2.6	22 "	4.2	15 "
3.1	18 "	4.9	6 "
4.0	10 "	5.7	2 "
4.4	7 "	6.4	nil
4.7	5 "	8.1	"

In general the curves are flatter the lower the coefficient. These results confirm the conclusions drawn from earlier experiments, namely, that a rubber vulcanised to give a coefficient exceeding 3.5 is certainly overcured, and cannot be expected to retain its physical properties for a reasonable length of time. To secure approximate permanency the coefficient should not exceed 3. The cure for the coefficient 3.1 with the ordinary sheet (1) corresponds with a curve resembling closely that for the coefficient 3.2 with the "slab" rubber (2), showing that, as regards these two types, at any rate, the coefficient is a fair indication of the lie of the curves.

Finally, it is clearly seen that the maximum breaking strain cannot be obtained without overcuring the rubber to such a stage that it commences to deteriorate within a few days of vulcanisation, and loses tensile strength at an average rate of about 1% per week.

The curves indicating the change in final length of the specimens (figs. 1B and 2B) are of a simpler

nature than the breaking strain curves because there is little or no tendency to an initial increase in elongation with period of ageing, and at the commencement the elongation is inversely as the

FIG. 2 B Unrolled Sheet.
Elongation.

coefficient. The curves are flatter and more nearly approach to the horizontal, the lower the coefficient. With coefficients under 3 or thereabouts, the curves approximate to the horizontal. The slope becomes more pronounced the higher the coefficient, and with high coefficients is very steep.

I am indebted to the Rubber Growers' Association for permission to publish this research.

THE INFLUENCE OF TEMPERATURE ON THE DECOMPOSITION OF SODIUM CARBOLATES AND CRESYLATES BY CARBON DIOXIDE.

BY G. J. DENBIGH, B.Sc.

The fractions of coal tar which contain the bulk of the tar acids are crude naphtha, light oil, and carbolic oil, and the crude acids are extracted from these by washing with caustic soda solution. The separation of the crude acids from the sodium salts is effected most economically by decomposing with carbon dioxide, thus regenerating sodium carbonate which can be again causticised and used for the further treatment of fresh oils. The crude acids thus obtained are neutralised and partly dehydrated by treatment with a small quantity of sulphuric acid.

In the course of superintending the working of a crude carbolic plant, the author noted the apparently abnormal decomposition by the carbon dioxide. This was made in a small lime kiln, and after purification usually contained 17–20% of CO_2 . Careful testing of the gas proved that a small variation in the percentage had little or no effect on the rate of decomposition, so attention was directed to the effect of temperature.

In the first instance gas was bubbled through an ordinary cresylate solution obtained from the plant, and it was at once evident that decomposition was

much more rapid at high temperature than at lower ones. More careful experiments were then arranged, using pure chemicals for the necessary solutions.

For this purpose phenol with a solidifying point of 40.5° C., *o*-cresol, sol. pt. 30° C., *p*-cresol, sol. pt. 35.6° C., and *m*-cresol were obtained, the purity of the latter being ascertained by Raschig's nitration test to be 99.4%. In each case the calculated amount was dissolved in 800 c.c. of a 10% solution of sodium hydroxide and the solution diluted until titration with *N*/1 sulphuric acid showed the solutions to be exactly 2*N*, using phenolphthalein as indicator. Carbon dioxide generated in a Kipp's apparatus was passed through a solution of sodium bicarbonate and collected in a gas holder. A measured quantity (2½ litres) was then slowly bubbled through 100 c.c. of the sodium phenoxide solution. This represented a considerable excess of gas. The phenoxide solution was afterwards shaken with 50 c.c. of benzene, in two portions; after standing for an hour the benzene separated into a well-defined layer. The undecomposed phenoxide was removed and 20 c.c. and 10 c.c. of a 10% solution of sodium hydroxide successively shaken with the benzene solution to re-form sodium phenoxide. After again allowing to settle, this was run off, heated to 80° C., cooled, and decomposed with 30 c.c. of a 25% solution of sulphuric acid, and the liberated phenol measured in a small graduated cylinder. These experiments were repeated with the same quantities at different temperatures, the results obtained being exhibited on the accompanying curves. The volumes of carbon dioxide used were

Graphs showing the influence of temperature on the rate of decomposition of sodium carbolate and cresylates by carbon dioxide.

corrected for temperature and pressure, and the temperature of the phenoxide or cresylate solution regulated by a thermostat. The chief difficulty found in the work was in separating the benzene solution, at least one hour being required for proper separation.

The results established are:—(1) That all the cresols are more easily liberated than phenol. (2) That the cresols only differ slightly, *m*-cresol being the most easily liberated, *o*-cresol the least easily. These results agree fairly well with the other known combining powers of the cresols. (3) That in the case of both phenol and cresols the decomposition is more complete when warm, and that the rate increases more rapidly with all the cresols than with phenol.

From these data it might be considered possible to separate cresol from phenol by fractional decomposition. This is possible to a certain extent; but, like fractional washing, which gives a carbolate containing some cresylate or a cresylate containing some phenoxide, it is by no means as complete as could be desired. Thus a carbolate containing

20% of tar acids of which 30% was phenol was decomposed in two stages; the crude tar acid obtained from the first part was distilled and found to contain 15% of phenol, that from the second part 45%.

Other experiments bearing on the same point gave the following results:—

In tar acids of carbolate	% Phenol In first part decomposed	In second part decomposed
43	22	63
30	15	44
35	22	46
12	4	19
10	4	14.6

These results are naturally incomplete, but it is hoped by further experiments to ascertain more accurately the relative proportions of phenol and cresol liberated in different stages of the reaction, and the possibility of separating them by working at a temperature of 90°–100° C.

In conclusion, I desire to thank Messrs. E. A. Brotherton and Co., Ltd., in whose laboratories the work was carried out, for permission to publish these results.

THE INTERCONNECTION OF ECONOMIC BOTANY AND CHEMICAL INDUSTRY.

BY EDWARD WHEELER, A.C.G.I., A.I.C.

(ABSTRACT.)

By economic botany is understood the study of those plants, cultivated or wild, which are or may become industrially important. The work of an economic botanist is firstly to investigate the characteristics of plants of ascertained or prospective value with the factors of yield and distribution; secondly, to determine how far the conditions of soil, manuring, and climate influence the yield and quality of the raw material obtained; and thirdly, to endeavour to improve the plant by seed selection or breeding experiments so as to obtain a strain best suited to different localities and ranges of climate, or most immune to diseases.

The aim of economic botany has been recently very tersely summarised by Rendle, who stated that "improvement from an economic point of view implies co-operation of the botanist and plant breeder. The student of experimental genetics, by directing his work to plants of economic value, is able, by means of agriculture and horticulture, to produce forms of greater economic value" (1).

A brief consideration of the problems met with in the manufacture of the principal products prepared by the different chemical industries from the raw materials furnished by the economic botanist will indicate how far economic botany has assisted chemical industry, and in what directions further work is desirable.

1. Vegetable dyestuffs.

One of the chief obstacles to the successful cultivation of the indigo plant, namely, its liability to the disease known as "wilt," brought about by the constantly wet condition of the soil, has been overcome by discovering the most suitable planting areas and seasons (2), and by breeding a strain of the plant immune to the disease (3). Again, the yield of indigo has been found to be dependent on the conditions favouring the maximum absorption of nitrogen from the air by the root nodules of the plant (4).

The recent work of Howard and Davis in India in studying the fermentation changes taking place in the vats, whereby the indigo is converted into indigo, has demonstrated the importance of control-

ling these changes for the production of a higher yield of dye and a more uniform product (5).

There are many other less important vegetable dyestuffs which by improved methods of cultivation, of breeding and selection of the plants, or of extraction of the colouring matter, might be successfully exploited, as in so many cases the crudest methods of production were still in use when coal tar dyes replaced the natural products.

2. Cellulose products.

Cellulose for industrial purposes is obtained from (a) the pecto-celluloses such as cotton, ramie, flax, and hemp, (b) the ligno-celluloses such as jute and the woods, (c) cereal straws and grasses.* The problems met with in the cultivation of the plants and isolation of cellulose may be briefly alluded to (6).

Cotton.—For the successful cultivation of the cotton plant (*Gossypium*) attention has to be paid to the climate and soil, as slight variations in these factors always give rise to variations in the cotton crops from season to season as regards yield of waste on spinning and general quality of the fibre. Recent work in Egypt has aimed at obtaining a pure strain of cotton plant which will yield cotton of greater regularity in length and tensile strength (7).

Flax.—In the case of flax (*Linum usitatissimum*) study has been devoted to the cultivation necessary to obtain good yields of both fibre and seed (8), the latter furnishing linseed oil. Research into the isolation of the fibre from the stems by retting—a fermentation process—has led to the use of pure bacterial cultures in order to obtain fibre of good quality and uniformity (9).

The grasses.—The grasses include the straws, bamboo, and esparto. Interest in the use of straw cellulose (10) has recently revived owing to the increased production of cereals in this country, while the utilisation of bamboo cellulose has been carefully studied by Pearson and Raitt in India (11).

The woods.—The study of the best conditions of growth in relation to climate and soil, rate of growth, pathology of trees, and allied investigations carried out by the Forest Departments will prove of increasing value to the cellulose industries (12).

Paper.—Constant investigations are being carried out by various workers and by the Imperial Institute as to the suitability of various vegetable fibres for papermaking. In time special crops may be cultivated solely for the production of papermaking materials (13).

Cellulose nitrates.—The cellulose nitrates are generally manufactured from waste cotton obtained from the textile factories. For nitration purposes uniformity of cotton is most important. It has been claimed that cotton produced in a cold, wet season does not nitrate so readily as cotton grown under more favourable conditions (14). Consequently improvements tending to give cotton of greater uniformity will also affect favourably the uniformity of the waste cotton.

Both cotton and wood cellulose have been used as raw materials for cellulose nitrate for artificial silk manufacture, though the "silk" made from the former was found to be superior to that made from the latter (15).

Cellulose xanthate.—Cellulose xanthate (known in solution as viscose) has been most successfully utilised for the manufacture of artificial silk, wood cellulose being the raw material employed (16). Variations obtained in tenacity and dyeing properties of artificial silk are sometimes ascribed to the original wood cellulose used. A study of the

best time of cutting the wood, the best type of tree, and its conditions of growth in relation to the wood cellulose produced from it would be of value in relation to papermaking and artificial silk manufacture.

3. Potash and iodine.

Our knowledge as to the most profitable kinds of waste wood and plants to exploit as sources of potash is very meagre, and there is much need for a systematic survey of the potash content of the ashes from such waste material. Thus it is only recently that the use of braeken and hedge clippings (17) and of banana skins and stalks (18) has been advocated for potash production.

Extended workings of seaweed for potash and iodine have been commenced recently in British Columbia and the United States, but the results so far have not altogether realised expectations (19). As Hendrick has pointed out, a survey of the seaweed supplies and their rate of renewal, the potash and iodine distribution in different varieties, and the best methods of isolating the products, are all questions to be answered if the industry is to hold its own economically (20).

4. Vegetable oils, fats, and waxes.

Amongst products prepared from natural oils, fats, and waxes, for soaps are required mainly a cheap and plentiful supply of suitable oils, for food products as margarine an almost colourless, odourless, and tasteless oil, for paints and varnishes good drying oils, and for lubricants non-drying or less strongly drying oils. The number of oils satisfying such requirements are many, and the work of the economic botanist is chiefly concerned with the question of increasing the existing sources of supply and studying the physiological processes underlying the nutrition of the plant, and the effect of fungoid and insect diseases in relation to their oil-bearing capacity (21).

5. Varnishes and lacquers.

The qualities required of an oil varnish are good colour, consistence, drying properties, lustre, durability, and flexibility. These are furnished *par excellence* by the fossil copals; but there seems no reason why, in the future, present day trees should not furnish as good material as the fossil products provided that the economic botanist or forest expert is able to control the methods of cultivation and tapping of the trees, so as to accentuate such qualities in modern resin (22).

There is a considerable need for physiological and chemical research in order to understand the conditions necessary for the formation and exudation of all resins and the changes undergone by them whereby they become of value as raw materials for varnishes and lacquers.

6. Indiarubber.

Hevea brasiliensis (23) has been carefully studied as regards the influence of climate, soils, manuring, straight *versus* forked trunks, etc., on the yield of latex and the best conditions and times for tapping (24). Generally it has been found that plantation rubber lacks uniformity and shows variations in its appearance, especially noticeable in its behaviour on vulcanisation.

As Dunstan pointed out in 1914 (25) the origin, nature, and functions in the tree of the latex, which carries the rubber, are not known precisely.

7. Vegetable tannins.

The scientific exploitation of the tannin-yielding plants has recently increased; thus in India the investigation of the best species of mangrove for the production of mangrove tannin has been undertaken (26), while in Natal *Acacia mollissima* has been

* The classification adopted is that given by Schwalbe in "Die Chemie der Cellulose," pp. 392, 459.

acclimatised and successfully cultivated, good yields of wattle tannin being obtained.

A considerable amount of work has also been done in Sicily (27), India (28), and America on the cultivation of sumac, questions as to the kind of planting, methods and seasons of harvesting, and age of plant being correlated with the yield of tannin, work which might be usefully extended to other sources of tannin.

A research into the physiological processes involved in the formation of tannins in the barks of woods would probably yield useful knowledge as to the best periods and methods of harvesting.

S. (a) Sugars.

The sugar cane (*Saccharum officinarum*) has been cultivated for many years in tropical countries, and much work has been done in determining the best conditions as regards the choice of suitable fertilisers (29), the selection of the best cane for different soils and climates as in Java (30) and India (31), yet a recent writer has observed that so little is known as to the essential botanical characters of the various types of sugar cane that experiments on Mendelian lines should be started, as at present no fixity of type can be assured, for even if improved canes are produced they disappear in eight years (30).

The cultivation of the sugar beet (*Beta vulgaris*) has been most successfully carried out in European countries, where as a result of continuous research work, the sugar content has been raised from 5–6% to 14–18% (32), while the ash content has been reduced from 3.8% to 2.7% (33). Experimental agriculture carried out in this country has shown that the beet can be cultivated here as successfully as abroad (33 and 34).

S. (b) Starches.

The chief source of starch for alcohol production is barley, which has been carefully studied with a view to the production of the most suitable kinds for the brewing industry (35). Other sources of starch for alcohol production are potatoes and maize (36), the starch content of which has been materially increased by pedigree selection and breeding experiments for the purpose. Reichert has suggested that by methods of breeding it may be possible to produce plants containing starch with the desired properties for textile works more pronounced (37).

9. Fermentation products.

The study of mycology is of great importance to chemical industry in two respects: firstly, in regard to the study of those fungoid diseases which so often affect the yield and quality of many raw materials; secondly, in regard to the study of those decompositions which can be more readily and cheaply brought about than by other agencies.

Besides alcohol, other products are obtained industrially by means of the bacteria or moulds; thus lactic acid is obtained from sugar by means of *Bacillus Delbrückii* and *B. longissimus*; acetic acid from alcohol by means of *Bacterium aceti*; while the moulds *Aspergillaceae* ferment glucose solutions producing citric and oxalic acids.

Doubtless in the future many more products will be made industrially by such agencies; thus, for example, the study of the fermentation of cellulose waste is almost an unexplored field, while the extended knowledge of well-known fermentation processes may be of great benefit to chemical industry, e.g., in the cases of indigo and leather.

10. Foodstuffs.

The conditions affecting the regularity of the growth of wheat are dependent on its supply of food, water, warmth, air, light, the absence of poisons and pests, the possession of straw strong

enough to support the plant, all of which have an influence in one direction or another on the strength of the flour (38). The work of Biffen and Howard on Mendelian lines in producing strains of wheat resistant to rust and giving the best results as regards yielding power and quality may be mentioned (39).

The methods involved in the cultivation and production of tea, coffee, and cocoa all necessitate careful control to enable the best quality to be put on the market.

11. Pharmaceutical products.

Alkaloids.—The amounts of the three principal alkaloids present in *Papaver somniferum*, morphine, narcotine, and codeine, vary according to the variety of plant, methods of cultivation, collection, and preparation of the raw materials adopted, questions which are being studied in India at the present time (40). In the case of the mydriatic alkaloids, considerable research work has been carried out in determining the influence of such factors as the effect of fertilisers (41), weather conditions, time of collection (42), and geographical area (43), on the content of alkaloid in the plant. Again by suitable selection the content of quinine in cinchona bark has been raised from 3% to 10% (44).

There is undoubtedly much work to be done in similar directions with other alkaloids, while the study of the mechanism by which the alkaloids are synthesised in the plants may be of great importance to the plant breeder (45).

Essential oils.—Work has been carried out recently in India (46) and by Baker and Smith in Australia (47) in the direction of surveying trees available as sources of oleo-resin. In studying the most suitable methods of tapping them, and the quality and yields of turpentine obtainable from such resins.

A very careful study of the distribution and quality of camphor obtained from trees of different age has been recently carried out by the U.S. Department of Agriculture (48)—work of great importance if the natural product is to compete successfully with its synthetic rival.

The botanical survey that has been carried out in the eucalypts by Maiden (49) and the chemical work by Baker and Smith (50) might with advantage be extended to many other species.

Generally in the essential oil industry there is much need for correlating the conditions of cultivation and breeding with the quantity and quality of the oil obtained. The metabolic processes underlying the production of the various constituents of the essential oils which in many cases render them so valuable are not understood (51). Moreover, the right period for separation of the oil will only be found from a study of the physiological changes taking place in the plant (52).

Conclusion.

Much work has been done by the Rothamsted and other experimental agricultural stations, by the different experimental stations connected with the rubber and sugar industries, by the different forest departments such as those in India (31) and the United States (53), and by the Imperial Institute. Nevertheless, the manufacturer has to deal with raw materials received from a distance and is consequently often out of touch with the cultivation and preliminary preparation of the raw material he receives and is unable to indicate directly to the economic botanist what his special requirements are. Hence the formation of a Raw Material Research Association would seem desirable for studying the problems connected with the cultivation, breeding, and diseases of plants and the furnishing of the supply of raw materials in relation to the requirements of the different chemical

manufacturers concerned, a special department or section being formed for each industry or raw material. In this way the interconnection of economic botany and chemical industry would be strengthened to the mutual advantage of science and commerce.

Edinburgh and East of Scotland Section.

Meeting held at Edinburgh on October 15th, 1918.

MR. D. R. DOTT IN THE CHAIR.

A SPECIAL BLEACHING POWDER FOR USE IN HOT COUNTRIES.

BY THEODORE KETTIE, D.Sc., J. LORRAIN SMITH, F.R.S.,
AND JAMES RITCHIE, M.D.

The use of hypochlorite solutions in surgery has now become world-wide, but great difficulty is encountered in tropical countries in preparing solutions of a definite composition owing to the instability of hypochlorite compounds. Ordinary commercial bleaching powder which, apart from electrolysed sodium chloride solutions, is the source from which all hypochlorites are derived, is unfortunately a very uncertain and unstable compound and deteriorates rapidly at temperatures considerably lower than those encountered in even moderately hot countries.

Summer temperature in Egypt varies from 98° F. (37° C.) on the coast to 117° F. (47° C.) in the Sudan: the deterioration of bleaching powder in Alexandria is so great that a sample assaying as low as 11% "available chlorine" is still regarded as of good quality. In a laboratory experiment we found that a sample which assayed originally 34% "available chlorine" when exposed to a temperature of 37° C. (98.6° F.) was reduced to 1% strength in 8 weeks, while at 45° C. (113° F.) and 50° C. (122° F.) the available chlorine had completely disappeared in three weeks and a fortnight respectively.

It is obviously impossible, without continual testing by chemical methods, to make up solutions for surgical or general disinfection purposes from a product which is steadily deteriorating, and in a field hospital testing is quite out of the question. We have been experimenting for a considerable time past with a view to produce a hypochlorite compound which could be relied on to give a fairly constant assay value under the conditions met with in the tropics and have succeeded in producing a bleaching powder which loses at a temperature of 45° C. from 3 to 10% of its efficiency in 3 months instead of, as with ordinary bleaching powder, losing the whole of it in 3 weeks.

Calcium oxychloride reacts in presence of water giving calcium hypochlorite and calcium chloride: the moisture in the bleaching powder therefore contains calcium hypochlorite and calcium chloride in solution, and it is the decomposition of this solution of hypochlorite which causes the instability of the bleaching powder.

The reactions involved are extremely complicated, but at ordinary temperature, *e.g.*, 15°–20° C., the main reaction may be represented by the equation

$$2\text{Ca}(\text{OCl})_2 = 2\text{CaCl}_2 + \text{O}_2.$$

At higher temperatures, *e.g.*, 45° C., the reaction is more complex: the main feature is the oxidation of hypochlorite to chlorate, but free chlorine and water are also formed. The formation of water is important as tending to hasten the decomposition of the remaining bleaching powder. The formation of chlorate is of considerable importance, as its presence is undesirable when the bleaching powder is to be used for sterilising drinking water.

In our first experiments we endeavoured to prevent the decomposition of the bleaching powder by removing the water by desiccation. It is very difficult to remove the last traces of moisture by this method and a considerable amount of chlorine is lost in the process. A good bleaching powder

assaying 31.95% available chlorine, when dried *in vacuo* over sulphuric acid at room temperature for three days, lost 6% of its "available chlorine," and this dried powder in sealed tubes when incubated at 37° C. for 2 months lost 92% of its "available chlorine." Another sample of the same powder was left at room temperature *in vacuo* over sulphuric acid for 8 months: at the end of that time it assayed 35.14% "available chlorine" and still contained 0.8% of moisture. This almost dry powder when heated to 45° C. for 10 weeks lost 50% of its "available chlorine," a decided improvement on ordinary bleaching powder which as before stated lost 100% of its "available chlorine" in 3 weeks. This desiccated powder was very hygroscopic, rapidly re-absorbing enough moisture to effect decomposition.

We then tried mixing an absorbent with the bleaching powder, and by using freshly ignited quicklime for this purpose, have succeeded in producing a dry powder which will stand a severe test. A mixture of freshly ignited quicklime with bleaching powder in equal proportions kept at a temperature of 50° C. for 6 weeks lost 9% and another sample of the same mixture at 37° C. lost only 4% of its "available chlorine" in 3½ months.

The bleaching powder on the market at the time these experiments were carried out, was not of such good quality as that obtainable before the war: the best samples we could procure assayed 33 to 35% "available chlorine," whereas 36 to 38% was the pre-war standard. The moisture varied from 9.5 to 16%.

Theoretically a bleaching powder containing 10% of moisture requires 31 grms. quicklime per 100 grms. to absorb the water: or a mixture of 76.4% bleaching powder and 23.6% lime should be quite dry, all the water having gone to form calcium hydroxide. The quicklime used in our experiments was prepared by igniting marble and contained 92% CaO, therefore the proportion for the above should be 74.4% bleaching powder to 25.6% quicklime, in actual practice better results are got if excess of lime is used: in this case the proportion should be 70% bleaching powder to 30% CaO.

Seven samples of bleaching powder were used in the experiments detailed in the tables: they are numbered A to G and are referred to in the tables under these letters—

		" Available chlorine "	Moisture
		%	%
Sample A	...	34.08	9.7
" B	...	33.37	12.6
" C	...	28.75	15.6
" D	...	35.5	16.0
" E	...	31.06	—
" F	...	35.14	0.8*
" G	...	28.0	— †

* Sample dried *in vacuo* over sulphuric acid.

† Bulk sample kept in cask for disinfection purposes.

Table I. gives details of some experiments with unmixed bleaching powders: they show very rapid deterioration and serve as controls to the experiments in Table II. The percentages of calcium chlorate in the samples are shown in the table as they are referred to later in connection with the sterilisation of drinking water.

Table II. is in three sections, giving experiments at 45° C. and 37° C., and also showing the difference in the results when the samples are in sealed glass tubes, or in corked bottles. The difference in the results in experiments 1 and 18 is very striking: both samples were made up at the same time and received the same treatment throughout, except that No. 1 was sealed up in glass tubes, and No. 18 was in a wide-mouthed bottle with a tightly fitting cork. There was a considerable pressure of gas

in the sealed tube after 15 weeks, the gas was colourless and contained hypochlorous acid: it is probable that the pressure of gas establishes equilibrium in the system and prevents further decomposition. This and other chemical problems encountered in the course of these experiments are being further investigated and will be dealt with in a subsequent communication.

Another point requiring further investigation is brought out in Exp. 7, sample D: this sample assayed 16% moisture and 35% "available chlorine" and when mixed with lime showed a distinct loss of strength, the 30% mixture assaying 22.36 "available chlorine" instead of 24.85 theoretical: in sample A with 9.7% moisture to 34% "available chlorine" the loss is not so great—the actual value is 23.07% instead of 23.85% theoretical. This reaction is of considerable importance and shows that it is advisable to choose a sample of bleaching powder containing as low a percentage of moisture as possible for preparing the quicklime bleaching powder mixture.

Referring to the figures in the column showing percentage loss of "available chlorine," two experiments, Nos. 4 and 7, show a much higher loss than the others: in both cases the amount of lime in the mixture was below the theoretical required for absorption of moisture in the samples. In the other experiments in Section I, where excess of lime was used, the decomposition was very much reduced. The figures in this column should be compared with those in the last column of Table I. As a general conclusion from the tables it may be stated that if a bleaching powder containing as low a percentage of moisture as possible is mixed with one-fourth more than the theoretical amount of freshly ignited quicklime necessary to absorb the moisture, a product will be obtained which, when suitably packed in air-tight containers, will withstand any temperature likely to be encountered in the tropics. The question of packing in bulk must be tried on a commercial scale, and arrangements have been made to have this done.

For the preparation of "Eusol" the new quicklime bleaching powder can be used without any difficulty: if allowance is made for the fact that the average value of the new powder (containing 30 to 40% CaO) is from 20 to 23% "available chlorine."

As remarked earlier in this paper, the presence of calcium chlorate in a bleaching powder which is to be used for sterilising drinking water is very undesirable owing to its unpleasant taste. In commercial bleaching powder the percentage of

chlorate is very small, and when the bleaching powder deteriorates at ordinary temperature very little chlorate is formed. Pattinson¹ showed that no chlorate was formed in 12 months at 15° C.: 1% was formed at 21° C.: and 3.7% at 26.5° C. Continuing the experiments at higher temperatures we obtained the following results:—9% of calcium chlorate formed in 8 weeks at 37° C.; 10.92% in 4 weeks at 45° C.; and 9.0% in 3 weeks at 50° C. The intermediate figures are given in detail in Table I.

A method employed for sterilising drinking water in the field is to add a definite quantity of bleaching powder to successively increasing measured quantities of water in suitable vessels till a point is reached at which the solution just reacts for free chlorine when tested with potassium iodide starch paper: from the data thus obtained the amount of bleaching powder to be added to the water tank is calculated. It is obvious from Table I. that at a high temperature deterioration is rapid and the amount of calcium chlorate formed is large. In applying this method in a hot country more bleaching powder is needed on each successive occasion and therefore more calcium chlorate is added till a point is reached when the water becomes absolutely undrinkable. Of the complaints which are made with regard to chlorinated drinking water the most bitter come from the Mediterranean area: this is probably due to the amount of chlorate which has been formed when the bleaching powder deteriorated at a high temperature. With quicklime bleaching powder the conditions are much improved, as may be seen from the figures in the last column on Table II. Waters were made up from different samples of ordinary and quicklime bleaching powder which had been exposed to high temperatures, and it was found that those from the bleaching powders containing 6 to 7% calcium chlorate were much more disagreeable than those from the quicklime powders, none of which contained more than 1.3% calcium chlorate.

Conclusion.—Bleaching powder in hot countries loses efficiency owing to the moisture present in the powder. If quicklime be added it combines with the moisture and to a large extent prevents decomposition of the hypochlorite.

The details set forth in the paper show that there is much room for improvement in the present method of supplying this important chemical to tropical countries. The treatment described has the advantage of a conservation of efficiency with a consequent saving in shipment.

¹ This J., 1888, 188.

TABLE I.

Exp. no.	Sample	T.m.p.	Percentages of "available chlorine" and calcium chlorate after exposure for						Loss of "available chlorine"	
			0 week	1 week	2 weeks	3 weeks	4 weeks	8 week	Per 100 grms.	%

MR. F. H. CARR IN THE CHAIR.

NOTE ON TRYPSIN, AND A NEW METHOD OF PURIFYING ENZYMES.

BY JOSEPH T. WOOD, F.I.C.

In a paper entitled "A new method of isolating trypsin," L. Holzberg¹ refers to some work carried out by Robertson,² who found that when one drop of a saturated solution of safranine is added to 5 or 10 c.c. of neutral, or very faintly alkaline, 0.5% solution of Grüber's trypsin, a light, flocculent, coloured precipitate slowly appears and gradually settles. It was assumed that the substance precipitated by safranine is actually trypsin, since the supernatant liquid, although containing substances precipitated by alcohol, is practically free from enzymes. Holzberg has repeated Robertson's experiment. To solutions of Grüber's trypsin, Fairchild's trypsin, and aqueous extracts of sheep's pancreas, he added three-eighths of the volume of a 0.8% solution of safranine. The precipitates were collected and washed, and their proteolytic action tested by digesting with a solution containing 2 grms. of casein (Gross test). The results are given in the following summary:—The substance which is precipitated by the addition of safranine to aqueous solutions of Grüber's or Fairchild's trypsin, or to aqueous extracts of pancreas, has a strong proteolytic action, contains safranine, is very sparingly soluble in water, and insoluble in organic

solvents. After the substance has been removed from aqueous solutions of commercial trypsin or pancreas extract, a considerable quantity of a substance remains in solution, which is precipitable by alcohol, and in the case of pancreas extract, a further precipitate is obtained by means of an alcohol-ether mixture (3 to 1). These substances are practically devoid of proteolytic activity.

I repeated this experiment by adding a 0.1% and also a saturated solution of safranine to various infusions containing trypsin. An aqueous extract of the pancreas gave a considerable precipitate, which behaved in exactly the same way as the precipitate obtained by Holzberg. Instead of using the Gross test, I used the gelatin test (this J., 1912, 1105). I found it impossible to separate the precipitate from the filter, as it dried into a horny film. The paper was therefore cut up into small pieces, and in order to obtain some quantitative data it was cut into one-inch squares, which were weighed, and these were then ruled into 100 divisions and the small squares placed in the gelatin tubes. It was found that six squares liquefied, but five did not. The approximate weight of precipitate on one square inch, assuming it to be uniform, was 5.5 mgrms. The precipitate on 0.01 sq. in. would therefore be 0.055 mgrm., so that the quantity of dry precipitate which is active lies between 0.33 and 0.27 mgrm.

Since the whole of the gelatin was liquefied, it was evident that the substance causing the liquefaction was soluble, and it therefore seems that Holzberg, by washing his precipitate, has removed considerable quantities of enzyme. On repeating the experiments with one of my own trypsin preparations, which was comparatively free from albuminous matter, I was surprised to find that no precipitate was formed, i.e., the ordinary preparations of trypsin, and aqueous extracts of pancreas, gave precipitates, but the purified preparation (the strength of which was equal to that of the crude

¹ J. Biol. Chem., 1913, 14, 335.

² J. Biol. Chem., 1907, 2, 317.

preparation) gave no precipitate. It appears, therefore, that the matter precipitated by safranine is an albuminous compound, which carries the enzyme down with it, and that the precipitation by this method does not produce an enzyme-safranine compound. The method appears to be analogous to that used by Cohnheim³ for the precipitation of diastase from saliva by means of calcium phosphate, in which a certain quantity of phosphoric acid was added to saliva and the liquid neutralised with lime water, which caused a copious precipitate of calcium phosphate. This precipitate carried down with it a large proportion of the proteins of the saliva, together with the diastase or ptyalin. The precipitate was then collected by filtration, and extracted with a volume of water equal to that of the saliva originally used. The diastase is slightly more soluble than the proteins, and accordingly passes into solution first. Cohnheim repeated this process several times, and finally precipitated the last extract by the addition of alcohol. This precipitate was collected, washed with alcohol, and dried over sulphuric acid, appearing then as an amorphous white powder, freely soluble in water. The author considered it to be free from proteins as its solution did not yield the usual reactions characteristic of these bodies.⁴

I have not yet had the opportunity to compare the nitrogen content of the purified trypsin with that of the trypsin before purification by the method I am about to describe. This would have an important bearing on the constitution of the enzyme.

On referring to Robertson's book on the proteins,⁵ I find that, speaking of his own work two years earlier, he says, in the course of a discussion on the compounds of proteins with dyes, "I have found that in faintly alkaline solution trypsin or some constituent of Grüber's trypsin (nach Spalteholz) forms an insoluble compound with safranine"; from this it appears that Robertson himself was doubtful whether the precipitate was a compound of trypsin and safranine.

The method of purification of the enzyme which I adopted is a very simple one, and so far as I know has not been previously described; it depends on the fact that cellulose absorbs the impure compound of proteins and enzymes, and that after drying, the colloidal protein portion adheres firmly to the paper, whereas the enzyme is very easily soluble. The method is as follows:—

Ordinary circles of Swedish filter paper (J. H. Munktel), 12½ cm. diam., area 122 sq. cm., ash 0.00095 grm., averaging in weight 0.87 grm. air-dry, were soaked in the impure enzyme solution, and dried quickly in a current of hot air. The average increase in weight was 0.054 grm., i.e., they contain about 6.0% of added matter, or 0.41 mgrm. per sq. cm. When such paper is placed in water, the enzyme dissolves quickly to a perfectly clear solution in a few minutes, but the colloidal matter with which it is associated adheres firmly to the paper; the solution is filtered after 15–20 minutes, by which time the whole of the enzyme matter is dissolved. If left for a longer time, proteins begin to dissolve, and the enzyme strength decreases.

When a solution of safranine is added to the enzyme solution prepared in this way, no precipitate is produced, and the solution passing through the filter is as active as the original solution, due account being taken of the dilution. The following experimental results were obtained:—1.8366 grm.

of the paper impregnated with enzymes was stirred in 183 c.c. of distilled water for 15 minutes, and then filtered; 0.6 c.c. of the filtrate was found to liquefy the standard gelatin tube under the same conditions as in the test previously described (this J., 1912, 1105), corresponding to 6 mgrms. of the paper. The 6 mgrms. of paper contained 0.34 mgrm. of original extract.

A test of the original extract showed 0.35 mgrm. of matter capable of liquefying the gelatin, but the soluble matter in the 6 mgrms. of paper was found by evaporation of the filtrates to be 0.23 mgrm., so that the enzyme has been purified to this extent; i.e. 35% of non-enzyme matter has been removed. For comparison it may be useful to give results for Grüber's pancreatin, which I have always used as a standard of comparison: it is labelled "Pankreatin Dr. G. Grüber & Co., Leipzig"; 0.1 grm. dissolved in about 30 c.c. of alkaline water digests 8–10 grms. of moist blood fibrin; 0.52 mgrm. of the original solution liquefied, and 0.56 mgrm. filtered through paper liquefied, i.e. my purified preparation is 2½ times as strong as Grüber's trypsin. It may be noted that about 20% of the Grüber trypsin was insoluble in water.

I do not suppose for a moment that the preparation I have made is a pure enzyme, and I have not been able to ascertain how far the purification can be carried by the above method, but I have reason to believe that the purer the enzyme the less colloidal is its character, and that it will pass through a membrane. Professor Kipping has kindly examined a solution of the purified enzymes with the polariscope in order to ascertain if it is optically active. The solution contained 0.1184 grm. of solids per 100 c.c., which was a strong solution from the point of view of enzyme activity, being about three times as strong as those I have usually employed. No rotation of the plane of polarisation could be detected in a 200 mm. tube. The following are the minimum quantities of material required to liquefy the gelatin in the test described:—Grüber's pancreatin (unfiltered), 0.56 mgrm.; do. (filtered), 0.52; safranine precipitate from pancreas extract, 0.30; pancreas extract on paper, 0.34; purified enzyme, 0.23 mgrm.

From the above facts I draw the conclusion that the enzyme itself is extremely soluble, whereas the protein matter with which it is associated is difficultly soluble, and this difference in solubility may be used to purify the enzyme.

DISCUSSION.

The CHAIRMAN said that most people who had attempted to purify enzymes had come to the conclusion that the more they were "purified" the less pure they became. That, however, did not seem to be the experience in this particular case.

Professor F. S. KIPPING said that he thought the discovery of Mr. Wood might be one of the most far-reaching importance. The difficulty of purifying enzymes was one with which workers were well acquainted, but it seemed probable that the new method would enable chemists to find out a great deal more about enzymes than they knew at present. It was remarkable that although the enzyme was so soluble it was completely precipitated and yet when the product was merely washed with water the enzyme was almost completely extracted.

Dr. R. M. CAVEN asked if the enzyme was precipitated along with protein matter, and if so was it a case of adsorption?

Mr. J. M. WILKIE, referring to the point raised by Prof. Kipping, asked if it was not likely that the phenomenon referred to was not wholly colloidal. It seemed not impossible that on drying, the protein was coagulated and so its solution rate suffi-

ciently diminished to enable a partial separation to be effected.

Mr. Wood, in reply, explained that the safranin precipitate was practically insoluble; when the precipitate was wet he considered that the enzyme adhered firmly to it, but when it was dry the enzyme dissolved rapidly. Referring to Dr. Cayen's and Mr. Wickle's remarks, he said that the phenomenon was undoubtedly one of colloidal adsorption.

DR. R. M. CAYEN IN THE CHAIR.

THE EFFECT OF HEATING OPIUM ON ITS MORPHINE CONTENT.

BY HAROLD E. ANNETT, B.SC. (LOND.), F.I.C., AND
HARDAYAL SINGH, B.SC.

(Agricultural College, Cawnpore, India.)

We have observed that if opium is heated in a water oven for some days the morphine content as determined by the B.P. process appears to be much lower than if the fresh sample is analysed in the moist condition and the moisture then allowed for.

Evan¹ refers to the loss of morphine which takes place on heating moist opium. Carles² has shown that opium extracts decompose on concentration at 100° C. Debourdeaux³ states that the amount of morphine in opium decreases with age, and that this decrease appears to be due to a chemical change. If this is so then one could expect a more rapid change to take place on heating. Lesure⁴ finds that morphine hydrochloride solutions undergo a change when heated, oxymorphine being formed but no apomorphine, and that the change is favoured by the presence of a minute trace of alkali. Feinberg⁵ agrees that no apomorphine is formed during the heating or storage of solutions of morphine or of its hydrochloride.

Experimental.

The morphine in a sample of well mixed moist opium was estimated by the B.P. 1914 and 1898 methods respectively, both on the fresh sample and after heating for six days in the water oven and then making up to the original weight with distilled water. The samples lost weight continually when heated. The results were as follows: 8 grm. sample, unheated 7.18%, after 6 days' heating 6.31% of morphine by B.P. 1914 method. 14 grm. sample, 7.15 and 6.36% respectively by B.P. 1898 method.

Three other samples of opium were then taken and a portion of each was spread on a glass plate and dried in the water oven. After one day the opium was scraped off the glass plate, ground to a powder, and sifted, and the drying continued for two days more. Another portion of each of the three samples was dried *in vacuo* over concentrated sulphuric acid at the air temperature. The samples were powdered as soon as they were dry enough and the drying continued. In all this took six days. The samples dried *in vacuo* were extremely hygroscopic. The morphine was then estimated in 8 grms. of each of the dried samples by the B.P. 1914 process. The following results were obtained:

Sample No.	Morphine content in dried opium	
	Sample dried in water oven	Sample dried <i>in vacuo</i>
1	6.86	9.68
2	7.52	9.57
3	8.20	10.36

Another sample of moist opium was analysed by the method of the B.P. 1914 in triplicate, both before and after heating in a water oven for 48 hours. After heating the sample and prior to the analysis the loss in weight on heating was made up by the addition of distilled water. The following results were obtained:

Sample No.	Percentage of anhydrous morphine found	
	Moist sample, unheated	Sample after heating for 48 hours
1	7.25	7.45
2	7.14	7.43
3	7.02	7.49

Here it would seem that heating for 48 hours has slightly increased the morphine content. Certainly it has not decreased it.

A series of experiments was next carried out to determine the effect on the morphine content of heating the opium for various lengths of time. The method of analysis used was that of the B.P. 1914. A mass of moist opium was thoroughly mixed and 26 portions of 8 grms. each were rapidly weighed off, each portion being spread in a thin layer on a glass plate. Two portions were analysed at once and the remaining 24 portions heated in the water oven. After one day two more samples were removed, the weight of each made up to 8 grms. by addition of distilled water, and analysed. Daily two more samples were similarly removed for analysis. The results were as follows:

No. of hours heated	Anhydrous morphine in moist opium		Loss in weight at end of heating	
	(a)	(b)	(a)	(b)
—	6.78	6.87	—	—
24	6.43	6.57	1.773	1.748
48	6.97	6.91	1.829	1.803
72	6.66	6.97	1.856	1.851
96	6.57	6.62	1.888	1.881
120	6.12	6.08	1.870	1.876
144	5.60	6.14	1.911	1.894
168	5.66	5.62	1.951	1.981
192	4.92	4.79	1.951	1.960
216	4.79	4.50	1.954	1.969
240	4.19	4.24	1.954	1.983
264	4.26	4.34	1.972	1.985
288	4.63	5.00	1.955	1.934

The heating has therefore had a very marked effect on the opium. This effect, however, did not become apparent until after four days' heating, from which time up to 264 hours there seems to have been a steady increase in the loss of morphine; during the subsequent 24 hours the morphine content appears to have increased. The figures showing the loss of weight on heating after the various intervals of time indicate that after the seventh day practically no further loss took place. This fact is of interest in that it indicates that the loss of morphine does not coincide with a loss of volatile constituents from the opium.

A series of experiments was designed to compare the results obtained when the opium sample is

³ J. Pharm. Chim., 1912, 6, 491.

⁴ J. Pharm. Chim., 1909, 30, 337.

⁵ Z. physiol.-Chem., 1913, 84, 363; this J., 1913, 32.

dried (a) *in vacuo* and (b) in a water oven with those obtained when (c) the sample is analysed in the fresh moist condition. For this four different lots of opium were taken, the method of B.P. 1914 being used throughout. After two days the samples in the vacuum desiccator (a) were powdered and returned to the desiccator until a constant weight was registered (7 days); the loss of weight was then made up with distilled water and the morphine estimated. The samples heated in the water oven (b) were powdered after three days and replaced in the water oven for 9 days, after which time the loss in weight was made up with distilled water and morphine estimated. The results were as follows:

Treatment	Anhydrous morphine in samples			
	No. 1	No. 2	No. 3	No. 4
	%	%	%	%
Dried <i>in vacuo</i> ...	8.12	5.66	4.11	3.17
Dried in water oven ...	5.43	3.16	1.63	1.16
Undried ...	7.50	5.36	3.62	2.57

The drying of the samples in the water oven for 12 days has therefore resulted in a much lower recovery of morphine. On the other hand, drying *in vacuo* appears to have slightly increased the amount of morphine.

We have as yet had no opportunity of inquiring into the nature of the change which the morphine undergoes. If, however, samples of opium are dried *in vacuo* or by heating in a water oven, we have observed certain marked differences in the resulting products. Firstly the heated opium is much darkened and the lime extract of heated opium, prepared as in the B.P. process, is much darker than the extract obtained from unheated or from vacuum-dried opium. Moreover the morphine precipitated from heated opiums is always contaminated with much black material. The physical character of the heated opium is also very different from opium which has been dried *in vacuo*. The latter on exposure to moist air absorbs moisture rapidly and the surface of some of the samples might almost be said to be deliquescent. In the case of samples dried in the water oven the absorption of moisture is very slow in comparison.

Conclusions.

1. Opium heated in the water oven at 97°–98° C. may suffer a large decrease in morphine content. We have found no trace of this effect during the first five days' heating, and therefore it can hardly affect results obtained by the B.P. method.
2. Opium when heated in the water oven suffers a marked change in its physical properties.

DISCUSSION.

Mr. H. DROOP RICHMOND said he thought there was no doubt that the loss of morphine on heating was due to oxidation: morphine could be converted completely to pseudo-morphine by peroxide, but he did not think that was a complete explanation of the non-hygroscopic property of the opium when dried at 100° C. as against the hygroscopic character when dried in vacuum. Five days' heating of opium was comparatively ineffective with regard to the morphine content. That was rather a long time for drying powdered opium, and in very much less than that time it lost its hygroscopic nature. That loss and the fall in morphine content were not due to the same cause. Some time ago they had observed in Messrs. Boal's laboratory similar phenomena to those described by the authors, and, as would be seen from Miss Iles' remarks, their results broadly confirmed those of the authors.

Miss L. E. ILES said that during the past few months she had made numerous estimations of the morphine content of Persian opium and had found that moderately prolonged heating (120 hours) in the water oven had not appreciably diminished the morphine content, thus confirming the authors' experience with Indian opium. After that period of heating the morphine content was found to remain practically constant, and in one case even showed a slight increase. The temperature of the water oven used was about 90° C., compared with the authors' 97°–98°. The following results were obtained, the alkaloid in each case being titrated:—

	After heating in water oven for	and in air oven (100° C.— 115° C.) for	Morphine %
SAMPLE A.	204 hrs.	12 hrs.	8.69
9.16% morphine,	241 "	20 "	6.52
8.36% moisture	276 "	39.5 "	5.51
	324 "	65.5 "	4.92
SAMPLE B.	120 "	12 "	10.2
10.62% morphine,	196 "	24 "	9.97
8.9% moisture	221 "	35.5 "	8.38
	256 "	58 "	6.70
	304 "	84 "	5.69

* 3 hours at 120° C.

For three hours of the second period of heating of A and the third period of heating of B, the temperature of the air oven was maintained at 120° C. Both samples were found to have charred slightly, showing in the case of A, 6.52% morphine and in the case of B 8.38%. From then onwards the temperature of the air oven was kept below 115° C. After the last period of heating of B, a gravimetric estimation was made according to the B.P. 1898 method, showing 6.2%. A portion of this alkaloid was titrated indicating 5.69% morphine. It should be pointed out that the alkaloid became darker in colour, and required much larger quantities of morphinated water to produce colourless washings, and was less readily soluble in acid water.

The CHAIRMAN said that it would be interesting to know if the loss of morphine began when the opium was drying, or whether the drying was complete in 4 or 5 days and the loss commenced then.

Mr. RICHMOND suggested that during the drying there was a good deal of water vapour present and oxidation was therefore slow.

Mr. J. M. WILKIE said that Indian opium had always suffered in comparison with the Smyrna variety because of its low morphine content. The Persian variety was intermediate between Indian and Smyrna. The paper appeared to have an important bearing upon the original morphine content of opium, and raised the question whether Indian opium of a higher morphine content could be produced by a modified method of curing. In the B.P. (volumetric) method of estimating morphine, the bulk of the resinous constituents was rejected owing to the formation of insoluble calcium compounds, and only bases strong enough to affect the selected indicator were taken into account: it was possible that if the alkaloids were weighed instead of titrated one might get some valuable information. Most of the moisture in opium was probably driven off in about 6 hours and probably all of it in 10 or 12 hours. It was well known that morphine was very readily affected by small amounts of alkali, and it was possible that the much greater susceptibility of Indian opium to heat was due to some such cause. Heated opium presented certain points of distinction in the morphine determination. Instead of a homo-

geneous suspension in the lime stage, dark coloured resinous masses separated which might occlude alkaloid. The resins might have a distinct acid effect on the morphine molecule.

Mr. E. H. BUTLER said that in his experience the loss in morphine value on heating Smyrna opium was not so great as with the Indian opium used by the authors. If moist heat reduced the morphine value to this extent, there must be an enormous percentage of morphine lost in making extracts by water heating.

Communication.

VALUATION OF FERTILISERS.

BY J. ALAN MURRAY.

The unit hitherto employed in the valuation of fertilisers was the ratio of price to percentage, and was used to assess the prices of other grades of the same material by multiplying it by the percentages of fertilising ingredients in them. This method of calculation, it will be seen, is merely simple proportion and may be expressed as:

$x' = \frac{x}{p} \times p'$, where x is the market price of the grade that contains p per cent. and x' is the estimated price of that which contains p' per cent; x/p is the so-called unit.

The system was simple and well understood, but when the necessity for controlled prices arose the narrow limits within which it is applicable appear to have been recognised for the first time. At all events it broke down utterly and had to be abandoned. It was at once perceived that manufacturers could not be expected to sell 20% superphosphate at half the price of the 40% grade, and that farmers should not be expected to pay twice as much for the latter as for the former.

In this system it was assumed (1) that the value (to the farmer) of a fertiliser is proportional to the percentage of fertilising ingredients in it, and (2) that the price varies as the value. Neither of these assumptions has any foundation in fact.

If a quantity of basic slag containing 40% of phosphate be mixed with an equal weight of sand, or other non-reactive substance, the mixture will contain 20% of phosphate and, when applied to the land, will produce precisely the same effect as half its weight of the original slag. It does not follow, however, that if the original slag were valued at £4 per ton the mixture should be valued at £2 per ton. Assuming that the expenses of application amounted to 25s. per ton (see note 1) in both cases, the value (to the farmer) of the mixture would be only 27s. 6d. per ton because the expenses of application are twice as much for the same amount of phosphate (see note 2). If the difference in percentage were greater than in the example above, the difference in value would be larger. The "value" per ton of the 1% grade, i.e. the unit, would not be 2s.; it would be a minus quantity. In short, the cash "value" of fertilisers is not proportional to the percentage of fertilising ingredients; it depends upon the expenses of application (freight, cartage, etc.) and varies therefore with the circumstances in particular cases.

Obviously no reliable inference regarding the efficiency of fertilisers can be drawn from the prices of the same. It is equally impossible to infer market prices from the efficiency as estimated by chemical analysis or otherwise. Unquestionably the price that will be paid (in free markets) for any fertiliser increases with the effective value, which in turn depends upon the percentage of fertilising ingredients, but not necessarily, or usually, in direct proportion. Demand is only one of the conditions

which govern market prices. The fatal defect of the system of unit values was that it took no account of the supply price, which is governed by the cost of production.

Any scheme of valuation of which the object is to assess the prices of different grades of the same material must be based on the fact that the price, in free markets, comprises two elements, viz. (1) the cost of production, which may or may not be constant, and (2) another quantity which varies with the demand and, therefore, with the quality (percentage of fertilising ingredients). In general this is expressed by $x = k + np$ where x is the price, k the cost of production, p the percentage of fertilising ingredient and n is a coefficient which depends upon x and k . Since $np = [x - k]$ is the difference between price and cost it represents profit.

The schedule prices under the "Fertiliser Prices Order, 1918," reflect this view to some extent and may be used to illustrate it.

In the case of superphosphate, for instance, the schedule price is 92s. 6d. per ton for 15% grade and rises by 2s. 6d. per ton for each additional 1% up to 30%; beyond that point the price rises at the rate of 4s. per ton up to 44%, the highest grade affected by the Order. Within the limits specified these variations in price are concisely expressed by:—

$$(1) x = 92.5 + 2.5(p - 15) = 55 + 2.5p$$

$$(2) x' = 130.0 + 4.0(p - 30) = 10 + 4.0p$$

where x is the price, in shillings, and p is the percentage.

When $p = 30$, $4p + 10 = 2.5p + 55$ and the price of that particular grade may be calculated by either formula; it is 130s. per ton.

The schedule prices include cost of carriage by rail, estimated at an average of 12s. 6d. per ton. This amount has been added to the price and for present purposes should be treated as part of the cost of production. If it is deducted we must put $x - 12s. 6d. = k - 12s. 6d. + np$. The above formulae for the prices of superphosphate, if altered in this way, become:—

$$(1) x = 2.5p + 42.5 \text{ and } (2) x' = 4p - 2.5.$$

Similarly, the schedule prices (including carriage) of basic slag may be expressed by:—

$$(1) x = p + 48 \text{ and } (2) x' = 1.5p + 37.$$

For sulphate of ammonia the formula is: $x = 15p - 13.5$.

It will be seen that in each case the price is made up of two quantities corresponding to k and np respectively. It must not be assumed, however, that the values found for k in these equations necessarily represent the actual cost of production. The method by which they were deduced and the fact that two widely different values—one of them a minus quantity—have been found for k in superphosphate, preclude any such inference. This does not imply that the prices themselves are not fair and reasonable. It means, merely, that the "Order" is not a scheme of valuation and that no attempt has been made to resolve the prices accurately into their elements. The values assigned to n in the schedule prices are purely arbitrary and the difference $(x - np)$ is not therefore the true value of k . In formulating a scheme of valuation the procedure must be reversed; the actual cost of production must first be ascertained and the value of n deduced by $n = (x - k)/p$.

The cost of production can only be ascertained from data supplied by the manufacturer. In the case of superphosphates it includes (1) rent or royalty payable to the owner of the raw phosphates, (2) cost of excavating and shipping the same to this country, (3) cost of treatment (grinding, acid, labour, plant, establishment charges, etc.), and (4) cost of packing and distribution if payable by the producer. Items 1 and 2 do not, as a rule,

vary much within a limited period, *e.g.* a single season. The difference in cost of treatment for grades below 30% is probably insignificant and *k* should therefore be constant. The cost of treatment for the higher grades rises progressively and *k* must be increased accordingly, whereas *n* should remain the same throughout.

In the formula deduced from the schedule prices of superphosphate, *k* is constant for all grades from 15 to 30%. Assuming for the moment that this value for *k* (55s. per ton including carriage) is the actual cost of production and that $2.5p$ accurately represents the effect of demand on the prices, the value of *k* for the several grades mentioned below would be as follows (see note 3):—

grade	20%	25%	30%	35%	40%	45%
<i>k</i>	55	55	55	62.5	70	77.5

It will be seen, therefore, that for 30% grade $x = 2.5p + 55$ and for 40% grade $x = 2.5p + 70$.

The cost of production of basic slag is not so easily determined. It may be debited with part of the cost of the ore, lime, fuel, etc.; or it may be regarded strictly as a by-product chargeable only with the cost of grinding and packing, the balance of the price being treated as profit. For the purposes of a scheme of valuation the latter would appear to be the more correct as well as the simpler view. Adoption of it would not, of course, preclude the producer from using part of this profit to reduce the price of or to increase the apparent profit on the other product. The effect of adopting the suggestion would be merely to lower the value of *k* and thus, automatically, to raise that of *n*. If *k* were reduced to zero *n* would become the obsolete unit value.

As in the case of superphosphates the actual cost of production of the lower grades (up to about 22%) of basic slag is probably nearly constant; the cost of production of the superior grades is higher but it does not increase progressively as it appears to do, or may be made to appear, from the schedule prices. Thus, if $x = p + 48$ represents the proper subdivision of the price of the lower grades, the value of *k* for the several grades mentioned below would be as follows (see note 4):—

grade	12%	18%	22%	28%	32%	38%	42%
<i>k</i>	48	48	48	51	53	56	58

It will be seen therefore that for the 22% grade $x = p + 48$ and for the 42% grade $x = p + 58$.

The price of sulphate of ammonia previously mentioned is subject, under the Order, to an addition of 10s. per ton every three months from the end of August to the end of May. In effect this is due to the greater demand for the product as the season for its use approaches. The increase should therefore go to augment *n*, not *k*. For trade purposes it is probably not necessary or advisable to embody this addition in a formula, but in order to make its incidence clear we may put $(x+10) = (13p+10) = 13.5$.

Both buyer and seller will probably profess indifference as to whether a given alteration in price be called *k* or *n*, and truly, in any particular case, or in a schedule of particular cases, it matters not at all. But in order to formulate a scheme of valuation, the object of which is fairly to assess the prices of different grades of fertilisers, it is essential to know the causes of variation of the prices and the manner in which they operate. It is, in fact, precisely because it was not based on this principle that the system of unit values failed of its purpose. The application of the principle to the more complex cases of guanos and mixed fertilisers presents no obvious difficulty, but the work can only be successfully accomplished by or in co-operation with those who are thoroughly conversant with the trades concerned.

As every farmer is aware, the criterion of cheapness is not the price of a fertiliser but the ratio of price to percentage, *i.e.* the old-fashioned "unit."

In the notation used in this article the unit is x/p [$=k/p+n$] and it is clear that if *k* and *n* are constant the unit will diminish as *p* increases. The highest grades will therefore be the cheapest though they are the most costly. The same is true even when *k* increases progressively unless it increases faster than *p*. The unit values (x/p) of several grades of superphosphate, basic slag, and sulphate of ammonia, calculated from the schedule prices, including carriage, are given below:—

Grade	"Unit values"		
	Superphosphate	Basic slag	Sulphate of ammonia
	s. d.	s. d.	s. d.
12%	—	5 0	11 10
15%	6 2	4 2	12 1
20%	5 3	3 5	12 4
25%	4 8	3 0	12 5
30%	4 4	2 9	—
35%	4 3	2 7	—
40%	4 3	2 5	—
45%	4 2	—	—

These results are even more striking when plotted in graphic form.

Note 1.—Under the head of expenses of application are included all expenses other than the price of the goods, *viz.* freight charges, cartage, and spreading, here estimated at 12s. 6d., 6s. 6d., and 6s. per ton respectively, or 25s. per ton in all. Freight and cartage charges vary widely in different cases; 12s. 6d. is the average assumed for the former in the "Fertiliser Prices Order, 1918"; 6s. 6d. for cartage is the estimate of a farmer located about three miles from a railway station, and 6s. for spreading is also a farmer's estimate. It was necessary to take some definite figures for purposes of illustration, but the argument does not depend upon the accuracy of those selected or upon their applicability to particular cases.

Note 2.—If the price of the slag, *f.o.r.*, is 80s. per ton and the expenses of application 25s., the total cost is 105s. per ton, or 52s. 6d. for half a ton, which contains the same amount of phosphate as one ton of the mixture. But as the expenses of application are the same (25s.), in order to balance the account, the farmer could only afford to pay [52s. 6d. - 25s. =] 27s. 6d. per ton for the goods. In other words the mixture would be worth, to him, only 27s. 6d. per ton because he could obtain the same fertilising effect at a total cost of 52s. 6d. by purchasing half a ton of the original slag.

Note 3.—If $x = 2.5p + 55$ accurately represents the proper subdivision of the price for the lower grades of superphosphate, the formula $x = 4p + 10$, which is applicable to the higher grades, should be altered as follows:—

$$\begin{aligned} 4p + 10 &= (2.5p + 1.5p) + (55 - 45) \\ &= (2.5p + 55) + (1.5p - 45) \\ &= 2.5p + 55 + 1.5(p - 30) \end{aligned}$$

$$\text{when } p = 40, x = 2.5p + 55 + 1.5(40 - 30) = 2.5p + 70.$$

Note 4.—If $x = p + 48$ accurately represents the proper subdivision of the price for the lower grades of basic slag, the formula $x = 1.5p + 37$, which is applicable to the higher grades, should be altered as follows:—

$$\begin{aligned} 1.5p + 37 &= (p + 0.5p) + (48 - 11) \\ &= p + 48 + 0.5p - 11 \\ &= p + 48 + \frac{1}{2}(p - 22) \end{aligned}$$

$$\text{when } p = 42, x = p + 48 + \frac{1}{2}(42 - 22) = p + 58.$$

DR. CHARLES A. KEANE IN THE CHAIR.

COMMERCIAL "CONCENTRATED AMMONIA-LIQUOR" AND ITS IMPURITIES.

BY H. G. COLMAN, D.S.C., PH.D., AND E. W. YEOMAN, B.S.C., A.R.S.M., A.R.C.S.O.

Commercial "concentrated ammonia" is manufactured from the crude gas-works or coke-oven ammoniacal liquor in two qualities. The first of these qualities is obtained by distilling the liquor with addition of lime in the usual way, and condensing the distillate, and contains most of the hydrogen sulphide and carbonic acid and of the other volatile impurities of the original liquor, and is therefore largely a solution of ammonium sulphides and carbonates. The ammonia strength of this quality cannot be made more than about 16-17%, owing to the large amount of carbonate present, which at higher strengths crystallises out, causing stoppages in the manufacturing plant, and deposits in the vessels in which the liquor is stored.

The second quality is manufactured on a much larger scale, and consists for the most part of free caustic ammonia, the carbonic acid being more or less completely removed, as well as most of the other volatile impurities, but it still contains material percentages of hydrogen sulphide, the amount of which is usually required not to exceed 0.5%. The ammonia strength of this quality is about 25%.

This type of concentrated ammonia has for a long time been manufactured in considerable quantity as an "intermediate" product, being employed in the ammonia-soda manufacture, and in the manufacture of ammonium salts other than the sulphate, for which purposes a limited amount of hydrogen sulphide is not a serious objection, and is more than compensated for by the lower price of the product. The output of this type of concentrated ammonia has been very greatly increased owing to the requirements for ammonium salts for war purposes, but it has been found that in the manufacture of certain ammonium salts from it, especially the nitrate, difficulties may occur from the minor impurities present, and in particular from cyanogen derivatives. The present paper gives some account of the extent and nature of these minor impurities, and the variations found in samples from different plants.

The starting point for the manufacture is in most cases the crude ammoniacal liquor obtained by the carbonisation of coal in gas-works or coke-ovens, which usually contains an amount of ammonia varying between 0.9 and 2.2%; about four-fifths of this ammonia is present as sulphides and carbonates and is all evolved by simply boiling the liquor, as is also any small amount of ammonium cyanide which may be present. The remaining fifth of the ammonia is present in the form of salts with non-volatile acids, and chiefly in the form of thiocyanate, thiosulphate, sulphate, and chloride, and the ammonia thus combined is only evolved on distillation when sufficient fixed alkali (usually lime) is added to combine with the whole of the fixed acid radicals present. In addition the crude liquor always contains appreciable amounts of phenols and pyridine bases.

In general outline, and without going into manufacturing detail, the method of manufacture of the

25% ammonia is as follows:—The crude liquor, freed from all fatty matter, is first passed through a preheater wherein it is raised approximately to its boiling point, at which temperature the ammonium sulphides and carbonates undergo dissociation, and the greater part of the hydrogen sulphide and carbon dioxide is driven off, but these are accompanied by only a small proportion of ammonia; under the above conditions, this remains for the most part dissolved in the solution. The ammonia carried away with the effluent gases is recovered by washing the water or by other suitable means.

The hot liquor from the preheater, thus largely freed from hydrogen sulphide and carbonic acid, then passes to the ammonia still of the usual vertical type, in which the liquor travels downward from tray to tray, meeting as it falls an ascending current of steam which bubbles through it in each tray, lime being added (in the lower portion of the still in most cases) in sufficient quantity to liberate the whole of the "fixed" ammonia. The ammonia, steam, and volatile impurities pass from the top of the still to a reflux condenser, where a large proportion of the steam condenses with some ammonia, the condensate returning to the still; the bulk of the ammonia passes on to a further condenser where it is completely cooled and dissolved in water. Naturally considerable variations exist in the character of the plant used and in the method of working, but these matters are beyond the scope of this paper.

An examination has been made by the authors of a large number of samples of concentrated ammonia from different plants in all parts of the country, with the object, more especially, of ascertaining the amount and nature of the cyanogen compounds present, and some examination has also been made of the other impurities. Apart from the cyanogen compounds, the impurities found in appreciable quantity consist of the following:—

(1) *Hydrogen sulphide*. It is usually specified that the amount of this impurity shall not exceed 0.5%, and in the majority of samples examined, the quantity varies from this figure down to *nil*. A minority, however, contain much higher amounts, rising in one instance to 3.1%, evidently owing to insufficient elimination of the hydrogen sulphide in the preheating process.

(2) *Carbonic acid*. In many cases this is entirely absent, and is usually only present in small quantities, but in some instances up to 11% of CO_2 was found. Such high amounts are always accompanied by excessive amounts of hydrogen sulphide, and are due to inadequate treatment of the crude liquor in the preheater. For most purposes the presence of carbonic acid in moderate amount is not in itself objectionable, but when it is present in considerable quantity the amount of other impurities is always high.

(3) *Phenols*. The samples always contain phenols, derived from those present in the crude liquor, which are partly volatilised with the steam in distillation. No systematic determination of the amount has been made, but in a few samples tested the quantity varied from 0.11 to 0.37 grm. per 100 c.c., averaging 0.23 grm.

(4) *Pyridine*. Pyridine bases are always present, the amount found in a few samples varying from 0.21 to 0.32 grm. per 100 c.c., averaging 0.26 grm.

(5) *Ammonium thiosulphate*. The freshly prepared liquor is probably free from this impurity, which is formed secondarily by oxidation of the ammonium sulphides. The analytical methods tend to give results which are slightly too high, but the figures obtained from about fifty samples of different origin indicate that the amount varies from 0.08 to 0.35 grm. $(\text{NH}_4)_2\text{S}_2\text{O}_3$ per 100 c.c., no

higher figure than the last having been obtained. These samples were, however, all tested within a few days of their manufacture, and the amount probably increases steadily when the liquor is stored with access of air, owing to the further oxidation of ammonium sulphides. At the same time, we are not aware that any complaint has been made of any prejudicial effect due to the presence of considerable quantities of ammonium thiosulphate in the liquor.

Cyanogen Compounds.

The especial point on which information was desired, was the nature and amount of the cyanogen compounds present in samples of concentrated ammonia from different plants, these having been found of considerable disadvantage in the manufacture of ammonium nitrate, for which purpose it was desired that the total amount of cyanogen, calculated as ammonium thiocyanate, should not exceed 0.01 grm. per 100 c.c.

In the liquor as first produced, the only cyanogen compound present appears to be ammonium cyanide, formed by the action of the hydrocyanic acid almost always given off with the ammonia from the crude liquor during distillation. In presence of ammonium sulphide, however, this ammonium cyanide rapidly undergoes further changes; as soon as the oxygen of the air gets access to the liquor, oxidation of the ammonium sulphides takes place, with formation especially of ammonium thiosulphate and polysulphides, the latter at once reacting with ammonium cyanide forming the thiocyanate. Further, the ammonium cyanide solution produced acts on any iron (especially steel or wrought iron) with which it may come in contact, whether in the manufacturing plant or in the containing vessels, forming ammonium ferrocyanide. Hence the liquor samples may contain ammonium cyanide, ferrocyanide, and thiocyanate, though the tendency is for the cyanide to disappear rapidly owing to conversion into the other two forms, and in many cases ferrocyanide is absent, the only recognisable cyanogen compound being the thiocyanate.

There is, however, a further source of thiocyanate other than the hydrocyanic acid evolved with the ammonia in the distillation, for it was found that, on standing, the total cyanogen content in all forms of the liquor undergoes a material increase. This is shown in the following series of tests made on the same sample of liquor after the lapse of different periods, the fresh sample being almost free from cyanogen derivatives:—

			Total HCN calculated as NH ₄ CNS	
Freshly prepared product	0.0054	grm. per 100 c.c.
After standing 3 days	0.0061
" 7 "	0.0167
" 11 "	0.0175
" 17 "	0.0228
" 24 "	0.0504
" 31 "	0.0301

The cause of this increase was found to be the small quantity of carbon bisulphide usually present in the distillation gases from the still, and formed from the ammonium thiocarbonate always present in the crude liquor, this being absorbed in the concentrated liquor with re-formation of ammonium thiocarbonate. The latter, on standing, undergoes slow change, forming, among other products, ammonium thiocyanate. This change is shown by the following series of tests, in which a solution was made up of 100 parts of pure 25% ammonia, 0.5% of hydrogen sulphide, and 0.1% of carbon bisulphide. If the whole of this carbon bisulphide were converted into ammonium thiocyanate, the amount of the latter in solution would amount to 0.1%. Shortly after the preparation of the solution, it was found that about one-fifth of the carbon bisulphide had already been

converted into thiocyanate, and on standing the amount increased, until after about 20 days the thiocyanate remained constant, one-third of the carbon bisulphide having then been converted into thiocyanate.

All results given in grms. per 100 c.c.

nil = not qualitatively recognisable in 100 c.c.

trace = qualitatively recognisable but not in sufficient quantity to estimate in 100 c.c.

Table I. gives the results for 10 samples from gas-works, and Table II. for 10 samples from coke-ovens. All the other samples tested give results falling generally within the limits of the 20 given in the tables.

It will be seen that in the samples as received the quantity of free ammonium cyanide is either nil, or only a very small amount, owing to its already having undergone complete or almost complete conversion into ferrocyanide and thiocyanate. Ferrocyanide is rarely present in any but small quantity in samples made from gas-works liquor, but is often present in much larger quantity in samples made

from coke-oven liquor, and the total hydrocyanic acid is on the average much higher in samples from coke-oven liquor than in those from gas-works liquor. In very few of the samples was the total hydrocyanic acid so low as the desired amount of not more than the equivalent of 0.01 grm. of NH_4CNS per 100 c.c.

The much higher amount of cyanogen derivatives in the concentrated liquor from coke-ovens probably arises largely from the fact, frequently pointed out in the Alkali Inspector's Reports, that crude coke-oven liquor itself contains much larger amounts of free ammonium cyanide than that from gas-works. This is mainly because, on gas-works, the crude liquor is usually stored for a considerable time before being distilled, and during the interval, by the action of the oxygen of the air, the free cyanide originally present is mostly converted into thiocyanate, whereas in coke-oven plants, the liquor storage capacity is usually small, and the liquor has to be distilled almost as soon as it is produced. But even where the crude liquor distilled contains no free cyanide, some hydrocyanic acid is nearly always formed by the distillation under normal conditions of working, and even if no hydrocyanic acid is produced, there may nevertheless be thiocyanate in the concentrated liquor after storage if any carbon bisulphide vapour is also evolved from the still.

Quite apart from the objections to cyanides in the finished liquor, their presence is very disadvantageous from a manufacturing point of view, as a solution of ammonium cyanide, even when very dilute, has a serious corrosive effect on iron, and especially on wrought iron and steel. Thus for example in one instance where steel tubes were employed in the reflux condenser, the condensate flowing back from the condenser to the still contained 0.00143 grm. of iron per 100 c.c. in the form of ferrocyanide, and though this amount looks small, the amount of iron removed thereby from the tubes was about 4 lb. per day, and these rapidly corroded through and had to be renewed.

In considering the relatively large amount of cyanogen compounds present in some cases, it must be remembered that in many instances the plants in use had to be hurriedly constructed, often with the utilisation of existing sulphate plants as far as practicable, and the samples of which analyses are given were in a number of cases of the product obtained before those in charge of the plant had had much opportunity of gaining experience in working, and with further experience the quantities will doubtless be much reduced. Some of the methods which have been adopted or might be tried to this end may be mentioned, although the information as yet available is not sufficient to say how far they will be generally efficient.

Unquestionably one of the most important points is the proper treatment of the crude liquor in the preheater, to ensure a good removal of the carbonic acid and hydrogen sulphide, as any hydrocyanic acid present in the crude liquor is also largely eliminated there with good working, and this is also probably true of the carbon bisulphide present as thiocarbonate. The changes taking place in the preheater present many points of interest from a chemical, and especially from a physico-chemical standpoint, and have recently been discussed by Parrish (Gas J., 1918, 144, 413).

A further matter which also largely affects the amount of hydrocyanic acid evolved in the still, is the addition of lime in sufficient quantity to ensure that at all times the whole of the fixed ammonium salts are decomposed, for if the lime is at any time insufficient for this purpose, considerable increase takes place in the cyanogen content of the liquor produced.

Quite apart from this point, deficiency of lime is very objectionable, as it results also in waste of

ammonia, which then passes away as fixed ammonium salts in the waste liquor.

A further plan which has been tried is the passing of a stream of air along with the steam through the ammonia still, the oxygen of which effects the retention of the hydrocyanic acid by converting it into thiocyanate, which passes away with the waste liquor. The following tests on a week's run on the same plant, first without any air, and secondly with the introduction of air, show the effect:—

Conc. liquor	Week's run without air	Week's run with air
	grm. per 100 c.c.	
H_2S	0.67	0.16
HCN as NH_4CN	0.0054	nil
" $(\text{NH}_4)_2\text{Fe}(\text{C}_2\text{O}_4)$	0.0011	trace
" NH_4CNS	0.0230	0.0108
Total HCN	0.0295	0.0108
Total HCN , calculated as NH_4CNS	0.0830	0.0304

The total quantity of cyanogen was therefore reduced to about one-third, and the amount of hydrogen sulphide simultaneously reduced to about one-quarter.

The introduction of air in this manner increases the volume of uncondensed gases passing away from the final condenser, these carrying an increased quantity of ammonia, and necessitating a rather larger scrubber to recover this ammonia. In this particular plant the existing scrubber was found of quite sufficient capacity for the purpose.

Finally the hot gases passing from the still may be treated between that point and the reflux condenser with some agent which will remove the hydrocyanic acid. A mixture of ferrous sulphate solution and caustic soda has been quite successfully employed for the purpose, removing the hydrocyanic acid as sodium ferrocyanide, the concentrated liquor produced being free from cyanides, but the plan, under present conditions, has the disadvantage of a high cost for chemicals. In some plants a lime-washer is already introduced at this point to absorb hydrogen sulphide and carbon dioxide which have not been removed in the preheater, and the addition to the lime of sulphur as such or in the form of spent oxide tends also to retain the hydrocyanic acid as thiocyanate.

Analytical Methods.

The methods of analysis employed were in general those given by Linder (Alkali Inspector's Reports) for the analysis of crude ammoniacal liquor, modified where necessary to allow for the much larger quantity of ammonia present in the concentrated liquor.

In these analyses the greater part of the time required is taken up in filtration, the precipitates such as Prussian blue and cuprous thiocyanate being under ordinary conditions difficult to filter. The following procedure very greatly reduces the time required for filtration and washing, and is applicable with advantage in large numbers of cases, where difficult precipitates have to be filtered and washed, but have not subsequently to be dried and weighed, but are either to be rejected or treated with reagents to dissolve or decompose them.

The filtration is effected through filter paper pulp which is readily prepared by shaking torn filter paper in a bottle with water until it is pulped. A layer of the wet pulp is then poured on to a perforated porcelain plate in a funnel connected to an evacuated filter-pump flask, and after the water has been extracted the mass is gently pressed down with the finger. Occasionally, difficult precipitates such as Prussian blue may run through the filter at first, and in such cases they are completely retained by using only a moderate vacuum at the beginning and passing the first filtrate through the same pulp bed a second time.

Hydrogen sulphide.—This may be determined by Linder's method of precipitation with ammoniacal

zinc chloride solution, and treatment of the zinc sulphide formed with hydrochloric acid and decinormal iodine. For the concentrated liquor the following method was found more rapid:—10 c.c. of the sample is added to 50 c.c. of N/10 iodine solution mixed with more than enough hydrochloric acid to neutralise the whole of the ammonia, and the unused iodine filtrated with N/10 thiosulphate and starch, the difference giving the iodine used. A further 10 c.c. is then treated with cadmium chloride to remove all hydrogen sulphide, and, after filtering through pulp, added to 10 c.c. of N/10 iodine and hydrochloric acid, filtrating back with N/10 thiosulphate. The amount of iodine used, which represents that taken up by substances other than hydrogen sulphide, is deducted from the amount of iodine found in the first test, the difference giving the number of c.c. of N/10 iodine corresponding to the H_2S in 10 c.c. of the liquor (1 c.c. of N/10 iodine = 0.0017 grm. H_2S).

Carbonic acid.—10 to 25 c.c. (according to the amount of CO_2 present) is run from a pipette into a hot solution of calcium chloride, avoiding as far as possible exposure to the air, from which the solution absorbs carbon dioxide. The beaker is covered and heated until the precipitated calcium carbonate granulates. This is then filtered and washed, the precipitated calcium carbonate dissolved in 25 c.c. of N/1 HCl, the unused hydrochloric acid being determined by titration with N/1 caustic soda, using methyl orange as indicator (1 c.c. of N/1 HCl = 0.0022 grm. of CO_2).

Phenols were determined by the iodine method given by Skirrow (this Journal, 1908, 58) for the estimation of phenols in crude ammoniacal liquor.

Pyridine bases were ascertained by the method of Pennock and Morton (J. Amer. Chem. Soc., 1902, 24, 377).

Ammonium thiosulphate.—An approximate estimation of this salt is obtained from the number of c.c. of iodine required by 10 c.c. of the liquor after treatment with cadmium chloride, as found in the estimation of hydrogen sulphide above. Each c.c. of iodine = 0.0148 grm. of $(\text{NH}_4)_2\text{S}_2\text{O}_3$. The results tend to be slightly high, owing to the other impurities such as the thiocyanate and phenols having some action on iodine.

Ammonium cyanide.—The exact determination of the true amount of free ammonium cyanide actually present in a bulk of either crude or concentrated ammoniacal liquor is a matter of considerable difficulty. This arises, not from inexactitude of the analytical method, but on account of the rapid manner in which the cyanide undergoes conversion into thiocyanate by the action of the air during the taking of the samples, storing them, and handling them in carrying out the test. All figures of the amount of free cyanide in samples which have been in contact with air, or have stood for any length of time before analysis, merely give the amount of cyanide still remaining unchanged, which may be quite different from that of the bulk sample. For many purposes the total cyanogen content of the concentrated liquor is the chief information desired, and this change of cyanide into thiocyanate is unimportant, as any hydrocyanic acid not estimated as cyanide is found as thiocyanate; in these cases, therefore, the simplest plan is to add a few drops of ammonium polysulphide to the liquor taken for analysis to convert all cyanide into thiocyanate, and to omit the cyanide determination.

When required, the following method of estimation of the cyanide has been found most suitable, but with all precautions it is very difficult to avoid some conversion of cyanide into thiocyanate.

100 c.c. of the concentrated liquor is taken, if possible directly from the bulk to be analysed, if not, from a sample taken and preserved from

contact with air as much as possible, and slowly run from the pipette into a flask containing about 150–200 c.c. of boiling water to which about 10 c.c. of N/1 caustic soda has been added. The water in the flask should have boiled for some minutes before the addition of the sample so as to ensure the removal of all dissolved oxygen. When the bulk of the ammonia has been driven off, a solution of 5 grms. of lead nitrate is added, and the mixture distilled for 20–25 minutes; the distillate is collected in water containing 25 c.c. of N/1 caustic soda, the end of the condenser dipping beneath the surface of the liquid in the receiver. All hydrocyanic acid present as ammonium cyanide is found in the distillate, which is filtrated with N/10 silver nitrate in the usual manner, adding a little potassium iodide as indicator (1 c.c. N/10 AgNO_3 = 0.0054 grm. HCN)*.

Ammonium ferrocyanide and thiocyanate.—A few drops of ammonium polysulphide solution are added to 100 c.c. of the sample, till the solution shows permanently the yellow polysulphide colour, whereby any cyanide present is converted into thiocyanate. After standing about 15 minutes lead carbonate is added to remove hydrogen sulphide, and the filtrate boiled with addition of about 10 c.c. of N/1 caustic soda till most of the ammonia is driven off. The addition of a fixed alkali before boiling is necessary, as ammonium ferrocyanide loses part of its hydrocyanic acid when its solution is boiled, and the previous removal of hydrogen sulphide is also necessary, as in presence of ammonium sulphide hot alkali causes a partial conversion of ferrocyanide into thiocyanate, thereby rendering the results for the former too low and for the latter correspondingly high.

The solution is made slightly acid with sulphuric acid, and a solution of ferric alum added drop by drop till it shows the distinctive colour of ferric thiocyanate. The solution is then filtered through pulp, which retains the Prussian blue formed from the ferrocyanide, and is washed with water containing some dissolved electrolyte such as sodium or potassium sulphate. (Washing with distilled water often causes some colloidal Prussian blue to pass through the filter.) The precipitate contains all hydrocyanic acid present as ferrocyanide, and the filtrate all that present as thiocyanate.

(With small amounts of ferrocyanide, it frequently happens that the colour of the ferric thiocyanate makes it difficult to see whether any Prussian blue has been precipitated, but this shows up distinctly on the filter-paper pulp after washing. Filtration should be carried out in all cases, as even quantities of Prussian blue which cannot be estimated, if left in, interfere with the end reaction in the subsequent titration of the filtrate for thiocyanate).

About 10 c.c. of normal caustic soda is poured on to the filter pulp containing the Prussian blue, which decomposes it, forming sodium ferrocyanide. This is washed out with water, the filtrate strongly acidified with sulphuric acid, and distilled according to the method of H. E. Williams (this Journal, 1912, 468), with the addition of a little cuprous chloride, when all the hydrocyanic acid distils over, and is collected in water containing about 25 c.c. of N/1 caustic soda, as in the determination of the cyanide, the distillate being similarly filtrated with N/10 silver nitrate. Williams' method has been found by a large number of tests, made with pure ferrocyanides, to give very accurate results, provided that the cuprous chloride used does not contain material amounts of cupric salts. A con-

* E. Linder has drawn our attention to the fact that in boiling with caustic soda, some cyanide may be converted into thiocyanate by thiosulphate if this is present.

venient method is to use a 10% solution of cuprous chloride in hydrochloric acid, some copper strips being kept in the bottle to maintain the whole in the cuprous state.

Ammonium thiocyanate.—Two alternative methods may be employed for estimation of the thiocyanate in the filtrate from the Prussian blue, the first being the quicker, but rather less accurate for an unpractised eye.

The first method consists in adding to the filtrate a further quantity of ferric alum, heating to 95°, and after five minutes, cooling well, then adding dilute nitric acid (free from nitrous and hydrochloric acids), and titrating by Volhard's method with *N*/10 silver nitrate until the red colour of the ferric thiocyanate disappears (1 c.c. of *N*/10 AgNO_3 = 0.0027 gm. HCN or 0.0076 gm. NH_4CNS). The solution in this case does not become colourless, but almost always retains a pink colour, due to the action of the ferric salts on the phenols present, and this makes the end-point of the titration rather less easy to decide, but with a little practice there is no difficulty in ascertaining the point where the colour due to ferric thiocyanate disappears.

To obviate this difficulty entirely, the second method, which effects the removal of the phenols and other impurities present, is preferable until experience has been gained in the titration by the first method. This method must always be employed if chlorides are present. In it the filtrate from the Prussian blue, which should be only slightly acid, is heated to boiling with the addition of more than sufficient sodium sulphite to reduce the whole of the ferric salt present to the ferrous state; if a large excess of ferric alum has been used for precipitation of the ferrocyanide a correspondingly large amount of sulphite is required. Copper sulphate solution is then added in excess, and the precipitated cuprous thiocyanate filtered through pulp, washed, and the pulp and precipitate stirred with a hot solution of caustic soda or sodium carbonate (free from chlorides) and filtered. The addition of a few drops of ferric alum solution to the alkaline solution (forming ferric hydroxide) often facilitates the filtering and washing of the mixture through pulp. The well-cooled filtrate is then acidified with dilute nitric acid (free from nitrous and hydrochloric acids), ferric alum added as indicator, and the titration with *N*/10 silver nitrate made as before till the colour of ferric thiocyanate disappears, the solution now becoming completely colourless.

If the amount of cyanide has been previously estimated the amount found must be deducted from that found as thiocyanate, as this figure includes all hydrocyanic acid present as cyanide in the original sample, owing to the preliminary treatment specified with ammonium polysulphide.

Check Tests.

A number of check tests have been made by adding known amounts of ammonium cyanide, ferrocyanide, and thiocyanate to pure 25% ammonia, small quantities of phenols being also added to the check solutions. In absence of hydrogen sulphide, very accurate results are obtained in the determination of the hydrocyanic acid present in all three forms, and in the total amount present when tested in the manner specified above, but when hydrogen sulphide is present, although the total hydrocyanic acid present is found correctly, the amount present as cyanide is always found too low, and that as thiocyanate correspondingly high. The following two examples, one with, and one without hydrogen sulphide, exemplify the results obtained:—

	(1)		(2)	
	H ₂ S absent	H ₂ S present	H ₂ S absent	H ₂ S present
NH ₃ (approx.)	25.0	25.0	25.0	25.0
HCN as NH_4CNS	0.0200	0.0200	0.0200	0.0189
HCN as $(\text{NH}_4)_2\text{Fe}(\text{CNS})_6$	0.0410	0.0437	0.0440	0.0137
HCN as NH_4CNS	0.0306	0.0308	0.0306	0.0316
H ₂ S (approx.)	nil	—	0.5	—
Phenols (approx.)	0.2	—	0.2	—
Total HCN	0.0946	0.0945	0.0946	0.0942

DISCUSSION.

Mr. P. PARRISH said that he had had occasion to use the air method for the fixation of cyanides and could confirm all the authors had said in regard to its efficacy. There was, however, one possibility in connection with the adoption of this method which might prove a difficulty. He did not know to what extent the authors recommended the application of air nor to what extent the volume of the waste gases leaving the dissociator increased, but it seemed to him that if the dissociator was in direct connection with the spent oxide burners, the hydrogen sulphide and carbon dioxide which were passing forward and which were burned in the spent oxide burners might bring with them an appreciable percentage of diluent gas in the shape of nitrogen and oxygen. That might constitute a distinct drawback from the point of view of intensive working of the sulphuric acid plant. That was a much greater difficulty than any which was likely to arise by reason of the association of air with the steam and ammonia, for which the authors suggested the enlargement of the reflux condensers. He had been hoping to hear from the authors some comments with regard to the application of this very comprehensive investigation to the possible utility of concentrated ammonia liquor in lieu of liquor ammonia in the process of oxidation of ammonia, by a platinum catalyst, to nitric acid. The majority of people who were operating ammonia oxidation plants at the moment were very loth to work with concentrated ammonia liquor. On the other hand, American experience was that neither the hydrocyanic acid, the hydrogen sulphide, the pyridine, nor the carbon dioxide had any inhibiting effect on the platinum catalyst. Personally he hoped to put into operation very shortly a plant working on commercial concentrated ammonia liquor, not specially purified, and that should give an opportunity of confirming a number of the data which had been brought forward in the paper. The intention was simply to operate a vaporiser through which the requisite quantity of air would be blown by a fan, and in that way it was quite conceivable there would be a very rapid oxidation of the ammonium sulphide with the consequent formation of ammonium polysulphide, and the fixing of any volatile hydrocyanic acid that might otherwise result. He would not be inclined to recommend, nor indeed would he countenance, the use of spent oxide for the fixation of the cyanides. When he had applied the air method three years ago he had suspected that it had caused a perceptible dilution of the gases going forward to the sulphuric acid plant and that interfered with the intensive working of the plant. He had therefore turned to the use of sulphur, which lent itself to ready application to the dissociator, but had found it was necessary to use something of the order of 1% of sulphur on the concentrated ammonia liquor in order to fix the cyanides to such an extent as to keep them below the limit of 0.01% as ammonium thiocyanate. That represented 22.4 lb. of sulphur with a sulphur content of about 99% purity. If spent oxide was used the sulphur content was only about 45% and that meant using something of the order of 50 lb. of spent oxide in order to secure the fixation of the cyanides to such an extent as to conform to the specification of the

Ministry of Munitions. He was certain that if the spent oxide had been used for a week difficulty would have been experienced by the blocking of the serrated edges of the decomposing still and much more frequent cleaning than usual would have been necessary.

He had had an opportunity of installing a vessel between the ammonia still and the dephlegmator, operating practically on the principle of the Williams thiocyanate process. The arrangement he had made was to insulate the vessel in order that it should retain its heat and thus prevent any undue condensation, and that was remarkably effective. He had been able to reduce the thiocyanate in the liquor to something of the order of 0.008%, so he quite appreciated that the addition of spent oxide, at the point at which he now understood the authors recommended its application, would be effective.

Prof. J. C. PHILIP, in connection with the analytical methods described, drew attention to the fact that ferric thiocyanate solutions were not stable, and emphasised the necessity of analysing these solutions within a comparatively short time of the addition of the ferric salt to the thiocyanate. The rate at which reduction of the ferric salt occurred was not by any means negligible. That was his experience when thiocyanate was in excess, and he imagined that the same precaution was necessary when ferric salt was in excess. In his experiments with ferric thiocyanate he had found a reduction of 10% in an hour at 25° C., but, of course, the conditions were not quite the same as in the authors' analytical procedure.

Dr. F. M. PERKIN said that the carbonic acid present in the normal concentrated ammonia liquor which was supplied commercially was driven off with the ammonia and was one of the bugbears of those who had to deal with platinum catalysts. It was not so much that trouble was caused to the catalyst itself but by the pipes and the compressors becoming blocked up with ammonium carbonate and carbamate, and it was necessary to put in purifiers in order to get rid of this. Probably also, if cyanides or cyanates passed forward they would have a deleterious effect on the catalysts. There was no doubt that ammonia liquor from gas was much more difficult to work with in a catalysing plant than pure ammonia liquor or ammonia produced from cyanamide. Very considerable difficulties had been met with in the plants which had to deal with the manufacture, on a large scale, of nitric acid, owing to the difficulty of the removal of the pyridine bases. Several methods were in use, but they all entailed cost and very considerable plant.

Dr. R. LESSING asked if, instead of the iron oxide mentioned by Mr. Parrish, which undoubtedly had to be added in the dissociator in considerable quantities, and which would also precipitate ferric hydroxide which would tend to block up the serrated edges of the stills, an iron sludge of ferrous hydroxide and carbonate would be useful. This could be added in quantities not much exceeding the actual quantity of hydrocyanic acid and would, he thought, effect the conversion of some of the hydrocyanic acid into ferrocyanide. It was a somewhat different proposal from that mentioned by the authors, in which the vapours from the still were actually scrubbed with a suspension of ferrous sludge.

Mr. H. HOLLINGS asked whether the fact that liquor from coke ovens contained four times the quantity of cyanogen compounds found in liquor from gas works, had been in any way connected

with the difference in the carbonising conditions in the two cases.

Dr. COLMAN said that he was glad to receive Mr. Parrish's confirmation of the beneficial result of passing air with the steam through the still. In respect to the addition of spent oxide, he gathered that Mr. Parrish's remarks referred to the addition of this material to the preheater or the still, whereas his own reference was to the addition of it to the lime washer, where this apparatus was interposed between the still and the reflux condenser. While spent oxide could be added to the lime washer where one was provided to remove hydrocyanic acid, he did not recommend it as a general practice, but only as an emergency measure. His own belief was that by proper attention to the preheater, and ensuring that a sufficiency of lime was added, together with the use of some air in the still, the hydrocyanic acid could be almost completely removed. As he had mentioned, many of these plants were put up as emergency plants, and many things had to be done which would not be recommended as a regular procedure, and this was one of them. The proper plan was, however, to try to arrange matters so that the hydrocyanic acid was retained in the still.

With regard to the point raised by Dr. Philip, whilst it was quite true, as Dr. Philip had shown, that under certain conditions thiocyanate underwent fairly rapid change when ferric salts were present, he had not found evidence of any such change under the conditions of the test in any interval likely to occur in practice between the filtration of the thiocyanate solution and its titration. With regard to the use of concentrated liquor for the catalytic nitric acid process, he had no knowledge as to the effects of the various impurities. This investigation had arisen through matters being referred to him in connection with the question of the presence of cyanides affecting the manufacture of ammonium nitrate, and the tests for other impurities were incidental, and rather for general information than with respect to any particular process. In respect to the use of iron sludge for removing the hydrocyanic acid from the still gases, whilst not wishing to speak too definitely, his experience was that iron sludge did not keep back the whole of the hydrocyanic acid unless a fixed alkali was also added, as the product was ammonium ferrocyanide, which in hot solution readily lost hydrocyanic acid, unlike the ferrocyanides of the fixed alkalis. In reply to Mr. Hollings he had not made as large a number of estimations of the hydrocyanic acid in coke-oven gas as in that from gas retorts, but so far as his figures went, the amount produced in the latter was distinctly greater. That in spite of this the amount of free cyanide in gas-works liquor was less than in coke-oven liquor was most likely due, as he had stated, to the gas-works liquor being stored for a much longer period than coke-oven liquor, during which time the cyanide was chiefly converted into thiocyanate.

ANALYSIS OF COMMERCIAL "PURE" BENZOLS.

BY F. BUTLER JONES, B.A. (CANTAB.), A.I.C.

Theoretical considerations. The depression of the freezing point of a liquid, caused by the presence of a dissolved substance, is, in general, proportional to the weight of solute dissolved in a constant weight of the solvent. Experiments carried out with benzene as solvent, and carbon bisulphide, thiophen, toluene, and paraffin as solutes, have shown that the depression of the freezing point of benzene, occasioned by the presence of up to 4%

of these substances, is nearly proportional to the weight per cent. of solute, i.e., to the weight per 100 parts by weight of solution. It is convenient, however, when dealing with a mixture of liquids, to express the composition in terms of volume percentages, i.e., in volumes per 100 volumes of solution. For liquids such as the above-named it can be shown algebraically that small volume percentages are nearly proportional to the corresponding weight percentages, so that within certain limits the lowering of the freezing point may be taken as being proportional to the volume percentage of solute.

From a mixture containing benzene, thiophen, toluene, and "paraffin" only, the carbon bisulphide and the thiophen can be successively and completely removed without any alteration of the quantity of the other constituents. It is evident that the removal of these substances produces an increase of the concentration of the remaining solutes, but, as will be explained later, this effect is negligible if the concentrations are small. There is thus provided a means of estimating the percentages of carbon bisulphide and thiophen, for the quantity of the former is proportional to the difference between the freezing points of the mixture before and after its removal, while that of the latter is proportional to the difference between the freezing points of the mixture before and after the subsequent removal of the thiophen.

The remaining liquid is a mixture of benzene, toluene, and paraffin. The amount by which its freezing point is below that of pure benzene ($5.48^{\circ}\text{C}.$) is a measure of the sum of the percentages of toluene and paraffin, i.e.,

$$\delta\theta = k_1 \times \text{toluene \%} + k_2 \times \text{paraffin \%},$$

where k_1 and k_2 are the freezing point depressions produced by 1% of toluene and paraffin respectively.

One equation, however, is insufficient to evaluate the two unknowns, toluene % and paraffin %. Another equation is required, and this is provided by the specific gravity. The amount by which the sp. gr. is lower than that of pure benzene (0.8848 at $15.5^{\circ}/15.5^{\circ}\text{C}.$) is also a measure of the sum of the quantities of toluene and paraffin, i.e.,

$$\delta \text{ (s.g.)} = g_1 \times \text{toluene \%} + g_2 \times \text{paraffin \%},$$

where g_1 and g_2 are amounts by which the specific gravity of pure benzene is lowered by the presence of 1% of toluene and paraffin respectively; g_2 , which is not truly constant, cannot be calculated from a knowledge of the specific gravities of benzene and paraffin, for the volume produced by mixing benzene and paraffin is greater than the sum of the separate volumes, the magnitude of the expansion depending upon the relative proportions. It may, however, be taken as constant for small percentages, and can easily be found experimentally. For the four unknowns, therefore, there are available four equations involving six determinable constants, and four observed quantities.

1. $\Delta\theta = e_1 \times \text{carbon bisulphide \%}$.
2. $\Delta\theta = c_2 \times \text{thiophen \%}$.
3. $\delta\theta = k_1 \times \text{toluene \%} + k_2 \times \text{paraffin \%}$.
4. $\delta \text{ (s.g.)} = g_1 \times \text{toluene \%} + g_2 \times \text{paraffin \%}$.

These equations can be solved graphically, and for this purpose a graph has been constructed giving the volume percentages of the four solutes in terms, not of temperature and specific gravity differences, but of observed temperatures and specific gravity.

Preparation of pure materials. The purest materials available for the determination of the constants were:—

Benzene, b. pt. (corr.) $80.3^{\circ}\text{C}.$, sp. gr. ($15.5^{\circ}/15.5^{\circ}$) 0.8846, prepared from chosen samples of commercially pure benzol in the following way. The carbon bisulphide was first removed by means of alcoholic potash, the alcohol being thoroughly washed out

with water. The residual benzene was then shaken with strong sulphuric acid until all traces of thiophen had been removed. It was then distilled through a dephlegmator, the portion distilling at a constant temperature being collected. It contained about 0.1% of paraffin as the only impurity.

Carbon bisulphide, b. pt. (corr.) $46.25^{\circ}\text{C}.$, sp. gr. ($15.5^{\circ}/15.5^{\circ}$) 1.2713, prepared from "A.R." material by shaking with mercury, followed by distillation.

Thiophen, b. pt. 84° – $84.5^{\circ}\text{C}.$, sp. gr. ($15.5^{\circ}/15.5^{\circ}$) 1.0703, prepared from Kahlbaum's pure thiophen by redistillation.

Toluene, b. pt. (corr.) $110.8^{\circ}\text{C}.$, sp. gr. ($15.5^{\circ}/15.5^{\circ}$) 0.8720, prepared from chosen pure toluol samples by a method similar to that used in the case of benzene.

Paraffin, b. pt. 93° – $97^{\circ}\text{C}.$, sp. gr. ($15.5^{\circ}/15.5^{\circ}$) 0.7231, prepared from a sample of pure benzol from a gasworks tar by exhaustive treatment first with approximately 5% oleum, and finally, in order to avoid the possibility of attacking the paraffin, with cold 100% sulphuric acid.

Determination of the constants. Mixtures of benzene with small quantities of the four solutes were carefully made up by weighing, and the freezing points determined. As a matter of interest, the molecular weights of the solutes were calculated. Those of carbon bisulphide and toluene averaged slightly higher than the formula weights. That of the paraffin appears to be about 105. Thiophen, as is well known, does not separate in the pure state, but as a solid solution of constant composition. The molecular weight of 131–133 was calculated from the data (formula wt. = 84).

The following figures were finally obtained, and were used in drawing the graph:—

Substance.	Depression of b. pt. of benzene caused by the presence of 1% vol./vol.	Depression of sp. gr. of pure benzene produced by presence of 1% vol./vol.
Carbon bisulphide ..	$0.94^{\circ}\text{C}.$ (C_1)	—
Thiophen ..	$0.465^{\circ}\text{C}.$ (C_2)	—
Toluene ..	$0.52^{\circ}\text{C}.$ (k_1)	0.0001 (g_1)
Paraffin ..	$0.425^{\circ}\text{C}.$ (k_2)	0.0018 (g_2)

Nature of impurities. The impurities in a well-washed sample of commercially pure benzol occur with one possible exception only in very small quantities. Unsaturated compounds should be negligible in amount or altogether absent; toluene, carbon bisulphide, and thiophen may be present to the extent of a few tenths per cent. "Paraffin," however, may vary from a small trace to as much as 3% in somewhat rare cases. It is highly probable that this paraffin varies in composition according to the circumstances under which it is produced (temperature of carbonisation, type of retort or oven, etc.). In one particular case, the paraffin occurring in the pure benzol prepared from a gas tar was isolated, and was found to have sp. gr. 0.7231 ($15.5^{\circ}/15.5^{\circ}$), and to boil over a range of $4^{\circ}\text{C}.$ from $93^{\circ}\text{C}.$ to $97^{\circ}\text{C}.$ From its physical and chemical properties it appears to consist of a mixture of hydrocarbons of the methane series with cyclic hydrocarbons of the polymethylene series. In spite of its relatively high boiling point, as much as 25–3% of paraffin may occur in a pure benzol having a distilling range (5% to 95%) of $0.5^{\circ}\text{C}.$ In this case the major part of the paraffin must distil with the benzene as a constant boiling mixture.

Application of the method. It is evident, therefore, that a method of analysis such as that described above can be applied to the case of commercial pure benzols. Up to the present time, in order to carry out the complete analysis of a sample of "pure" benzol, it would have been necessary to estimate the carbon bisulphide and the thiophen by gravimetric methods; the toluene by the fractionation of a large bulk of the sample to obtain a residue rich in toluene (the composition of which could be found from its distillation characteristics), and the paraffin either from the consideration of the

specific gravity of the sample after the removal of carbon bisulphide and thiophen, or by the removal of aromatic hydrocarbons by exhaustive treatment with sulphuric acid.

The proposed method has the advantage that by its aid an analysis can be completed within one day by the employment of simple operations. By suitable arrangement of the work, this rate is considerably increased when several analyses are carried on together.

The freezing point measurements. The following provides a means whereby small quantities of carbon bisulphide, thiophen, toluene, and paraffin may be estimated with little trouble, and with a fair approach to accuracy, the measurements required being three freezing points and one specific gravity. The freezing points are determined in the usual way, by means of any thermometer capable of giving readings accurately to $0.01^{\circ}\text{C}.$ over the range $0-5.5^{\circ}\text{C}.$ Since, on an average, a difference of $0.01^{\circ}\text{C}.$ corresponds with about 0.02% of impurity (0.01% in the case of carbon bisulphide), this is the theoretical accuracy of the method. Should the best thermometer available be one divided in $0.1^{\circ}\text{C}.$ readable to $0.05^{\circ}\text{C}.$, results can be obtained accurately only to 0.1% (0.05 in the case of carbon bisulphide). In this case of course the thermometer corrections must be known to $0.05^{\circ}\text{C}.$

The method of analysis. The ice points of the thermometer having been determined, the freezing point (F.P.1) of the sample is taken. The carbon bisulphide is then completely removed by treatment for not more than one hour with alcoholic potash, avoiding the use of an undue excess of alcohol, followed by three washings with water. The freezing point of the residual benzene free from carbon bisulphide is determined (F.P.2). The thiophen is then completely removed from the carbon bisulphide-free benzene, according to a method privately communicated by Dr. S. P. Schotz by shaking continuously for 2-3 hours with twice its volume of a cold solution of basic mercuric sulphate (Denigès' reagent), prepared by dissolving 5 grms. of mercuric oxide in a solution of 20 c.c. of concentrated sulphuric acid in 100 c.c. of distilled water and filtering the solution. The residual benzene is washed twice with cold water in a separating funnel, the water removed, the benzene filtered from suspended solid through a small filter, and its freezing point (F.P.3) and specific gravity at $15.5^{\circ}/15.5^{\circ}\text{C}.$ are determined. The specific gravity must be measured accurately to within 5 in the fifth decimal place, a degree of accuracy obtainable without difficulty if a good type of pycnometer is used, and if the temperature of the bath is known to $0.05^{\circ}\text{C}.$ In practice it is convenient to take 60-70 c.c. of the sample and remove the carbon bisulphide. The residual liquid is then divided into two portions, 20-30 c.c. being reserved for the determination of F.P.2. The thiophen is removed from the remaining 40 c.c. It is advisable in all cases to prove the absence of thiophen from the final residue by the isatin and sulphuric acid test.

Employment of the graph. The volume percentage (c.c. per 100 c.c.) of carbon bisulphide is obtained from the graph by reference to F.P.1 and F.P.2; the thiophen from F.P.2 and F.P.3; and the paraffin and toluene from F.P.3 and the specific gravity. Theoretically it is necessary to apply corrections to all the values obtained, to allow for the increased concentration of the other impurities incident on the removal of carbon bisulphide and of thiophen, but in practice the smallness of the quantities present and the limits of accuracy of the method render this unnecessary.

The effect of water. The material does not need to be dried after the various extractions, for water appears to be sufficiently insoluble in benzene, at temperatures near $5^{\circ}\text{C}.$, not to affect the freezing point. The liquid of which the specific gravity is

to be determined should, however, be dried with a pellet of calcium chloride.

Effect of other impurities. The condition essential to the successful application of the method is that impurities other than the above named shall be either absent altogether, or present in not more than the most minute quantity. The sulphuric acid test (90 c.c. of the sample shaken for exactly 5 minutes with 10 c.c. of 90% sulphuric acid) must not show more than a pure lemon-yellow colour; this indicates that the analysis may be performed directly on the sample as received. Should the acid test show a deeper colour, the sample must be washed for 5 minutes with 5% of its volume of 90% sulphuric acid, followed by treatment with caustic soda solution, and several thorough washings with water before proceeding with the analysis. The presence of undesirable impurities is also indicated by the appearance during the treatment with alcoholic potash of a strong yellow colour that appears also in the extracted benzene. Care must be taken that the alcohol used is sufficiently pure, for should it contain aldehydes, coloured resinous substances are produced, and these ultimately contaminate the benzene, which should remain colourless after treatment. For the same reason it is inadvisable to leave the benzene and alcoholic potash in contact for more than an hour. The effect of the impurities in an insufficiently washed sample is to increase the apparent quantity of carbon bisulphide. The thiophen estimation may also be affected to a smaller extent.

Results. The method has been tested on mixtures of known composition made up from the same materials (with the exception of the benzene) as those used to obtain the figures for drawing the graph.

(1) A known mixture of benzene, carbon bisulphide, thiophen, toluene, and paraffin (the benzene used contained 0.1% of paraffin).

	Taken	Found
F.pt.1 = $4.43^{\circ}\text{C}.$ Carbon bisulphide	0.206	0.21
F.pt.2 = $4.63^{\circ}\text{C}.$ Thiophen	0.499	0.47
F.pt.3 = $4.81^{\circ}\text{C}.$ Toluene	0.129	0.15
Sp.gr. = 0.8821 Paraffin	1.29 (1.19 + 0.1)	1.3

(2) A known mixture similar to (1), but containing in addition a small quantity of hexylene. The mixture was divided into two portions, one of which was analysed directly, while the other received a preliminary acid washing, as already described. The benzene used contained 0.33% of paraffin.

	Not acid washed	Acid washed	Taken	Not acid washed	Acid washed
F.pt.1	$3.95^{\circ}\text{C}.$	$3.99^{\circ}\text{C}.$	Carbon bisulphide	0.367	0.43
F.pt.2	$4.35^{\circ}\text{C}.$	$4.32^{\circ}\text{C}.$	Thiophen	0.565	0.46
F.pt.3	$4.56^{\circ}\text{C}.$	$4.55^{\circ}\text{C}.$	Toluene	0.115	0.11
Sp.gr.	0.88115	0.88115	Paraffin	1.97	2.0
				(1.64 + 0.33)	

(3) Sample of pure benzol.

Sp.gr. = 0.8862	..	Distillation range	= $0.4^{\circ}\text{C}.$
		(5% to 95%)	
		Sulphuric acid test	= yellow.
F.pt.1 = $5.06^{\circ}\text{C}.$..	Carbon bisulphide	= 0.03%
F.pt.2 = $5.09^{\circ}\text{C}.$..	Thiophen	= 0.69%
F.pt.3 = $5.37^{\circ}\text{C}.$..	Toluene	= 0.10%
Sp.gr. = 0.8845	..	Paraffin	= 0.15%

The method can also be applied in certain cases to well-washed commercial benzols, and for this reason the toluene graph has been extended to 3%; but in such a case the accuracy of the method is diminished. Should the quantity of toluene exceed about 3%, the method of analysis devised by Spielmann and Wheeler (this J., April 15, 1916, p. 396) is more widely and more easily applicable.

I wish to record with pleasure my thanks to Dr. Percy E. Spielmann for his continued interest and for the valuable advice which he has given during the preparation of this paper.

THE ANALYSIS OF ALUMINIUM ALLOYS AND METALLIC ALUMINIUM.

BY J. J. FOX, D.SC., F.I.C., E. W. SKELTON, B.SC., A.I.C.,
AND F. R. ENNOS, B.A. (CANTAB.), B.SC.

The extended use of aluminium alloys has directed attention to the methods of analysis of these alloys and several communications dealing with the subject have appeared recently. A paper by Withey (Institute of Metals, March, 1916) gives a fairly complete account of the methods for the determination of the important constituents and impurities in aluminium and its alloys. Stansbie (this J., 1917, 802) describes a method which is suitable for works but its use is limited, as will be shown later. Recently another paper has been published on the subject by Collitt and Regan (this J., 1918, 91); the process described by these authors is suitable for dealing with certain alloys made according to known specifications from pure materials, minor impurities being either absent or negligible in amount. The alloys with which we have had to deal, however, have been of varied composition and on this account we have had to select or devise methods by which all the constituents present can be determined both accurately and rapidly. We have therefore thought it desirable to give an account of the methods which we have found most suitable for *general* work, after considerable experience of the matter.

In those cases where only the more important constituents are to be determined, the processes described by us have no disadvantage, either in speed or accuracy, compared with the processes referred to above. On the contrary, a common alloy containing about 3% of copper, 13% of zinc, and free from manganese, nickel, and tin, can be examined by Method II. much more rapidly than by any process requiring precipitation of zinc sulphide. Where manganese, nickel, etc., are present the method is at least as rapid as any of the processes hitherto published.

It may be noted that the analysis of aluminium alloys containing tin has received little attention in the literature of the subject. A large proportion of the alloys examined by us have contained up to 2% of tin and occasionally more, while in others it is often present in small amounts, such as 0.2%. We have also found lead to be a very common impurity, generally in alloys containing a large proportion of zinc.

As will be seen, we prefer to determine copper electrolytically. In this connexion we should like to emphasise the importance of the use of hydrogen peroxide* in place of nitric acid during the electrolysis of copper in the analysis of alloys containing a large amount of zinc. By this means a bright copper deposit is obtained and the resulting solution contains no nitrates or ammonia, thus permitting of the subsequent electrolytic determination of zinc and iron in soda solution.

During our work we soon came to the conclusion that in order to obtain the best results the method to be used must be specially adapted for the particular type of aluminium alloy under examination, and for the purpose of analysis we distinguish three types.

Type 1. Metallic aluminium, *i.e.* unalloyed aluminium. The examination in this case is for all metallic impurities and for silicon. Since any single impurity rarely exceeds 1% in metallic aluminium, the main impurities should be determined to within $\pm 0.05\%$ and the determination of the lesser impurities should be subject to a much smaller error.

Type 2. Alloys containing up to 13% of copper, and zinc up to 3%. Tin, if present, is usually below

3%, and manganese, nickel, and magnesium may occur. All these constituents should be determined to at least within $\pm 0.1\%$, and generally more accurately. Impurities and constituents such as iron, lead, and silicon should be determined to at least 0.05%.

Type 3. Alloys containing up to 20% of zinc, copper up to 5%, and all other constituents not exceeding 1%. The zinc in such cases should certainly be determined within 0.2% and generally within $\pm 0.1\%$.

These limits may appear rather wide in some cases, but it is our experience that none of the methods hitherto proposed leads to any greater (or as great) accuracy, especially with the zinc.

Before proceeding to the determination of the constituents of an unknown aluminium alloy, it is advisable to make a rapid qualitative test in order to determine to which of the three types the metal belongs. If the metal is in bulk, a very fair indication can be obtained from the nature of the drillings. Unalloyed aluminium is difficult to drill with $\frac{1}{8}$ " drills. It tears away and clogs the drill. Alloys with a high copper and low zinc content drill fairly short and clean and the drillings have a bluish tinge. Alloys with high zinc content generally show some slight tendency to tear and the drillings are long and white. Alloys containing magnesium give long white drillings but there is no tendency to tear.

The qualitative test is carried out most expeditiously according to the following scheme. About a gram of the alloy is allowed to react with 40 c.c. of pure 10% sodium hydroxide solution, the action being regulated by warming or cooling the solution. When evolution of gas has ceased the clear solution, which contains the bulk of the aluminium and zinc, is decanted from the brown residual metal into another beaker, and a few c.c. of sodium sulphide solution are added to it. From the bulk of the precipitate a rough estimate of the zinc content can be formed. The residual metals in the first beaker are washed by decantation with distilled water and then dissolved in a little nitric acid. The resulting solution is neutralised with a little ammonia, acidified with hydrochloric acid, and the copper (the presence or absence of which is by this time evident) and other Group II. metals removed by the passage of hydrogen sulphide. Group II. metallic sulphides are filtered off, the filtrate is boiled to remove hydrogen sulphide, and then oxidised with a little bromine water and the iron and aluminium precipitated with ammonia and filtered off. Nickel if present yields a blue solution at this stage, and it must be removed by dimethylglyoxime. Ammonium sulphide is added to remove any zinc and the filtrate from the zinc sulphide tested for magnesium. It is unnecessary to examine specially for lead, manganese, and tin, as these are found in the ordinary course of analysis. Nickel should be tested for carefully, because if its presence is unsuspected, all results after Group II. in the main analysis will be vitiated unless special precautions are observed. Magnesium is present in most samples, but generally as a small harmless impurity, and its estimation is frequently not required. In very few cases have we found nickel in alloys of the third class, *i.e.* those containing a large amount of zinc.

The recorded methods for the analysis of aluminium alloys describe two ways of attacking the metal: (1) complete dissolution by means of acid, (2) partial attack by means of sodium hydroxide solution whereby the zinc and aluminium are stated to be dissolved. The second procedure is certainly advantageous, inasmuch as most (but not all) of the zinc and aluminium are separated from the bulk of the copper and iron. Tin if present is partly dissolved. Traces of iron and

* Mr. W. Brash, B.Sc., A.R.C.S., has informed the authors that he has employed hydrogen peroxide when determining copper by electrolysis in brass and bronze.

manganese may also pass into solution, as is indicated by the dark coloured precipitate sometimes obtained when sodium sulphide solution is added to the solution of sodium aluminate and zincate. We have made a series of experiments with aluminium alloys containing from 2 to 15% of zinc, many of the metals being in the form of fine sawings as recommended by Stansbie (*loc. cit.*). The alloys were boiled with 10% sodium hydroxide for periods varying from one half to six hours, and it was found that from 0.2% of zinc in the low zinc alloys to as much as 1.6% in the high zinc alloys, remained with the undissolved portion of the metal. We desire to call particular attention to the fact that any process for zinc relying solely on the extraction with soda will give low results, unless the zinc in the undissolved metal is determined. Moreover, if tin is a constituent of the alloy, electrolysis of the soda solution leads to deposition of tin with zinc. For this reason, we are of opinion that the most satisfactory general method of attacking the alloy is by complete dissolution of the metal.

None of the methods hitherto described gives any indication that there is serious difficulty in obtaining an accurate determination of tin. The process usually recommended is to dissolve the metal in nitric acid, evaporate to dryness, filter the insoluble matter, and weigh the tin oxide; but there are several difficulties in this procedure which call for comment. In the first place, aluminium alloys containing small proportions of copper and zinc are not easily dissolved by nitric acid and the evaporation to dryness of aluminium nitrate is not easy and requires a good deal of attention. Besides this, the resulting tin oxide is usually contaminated with silica and with iron and aluminium oxides. It cannot be assumed to consist of tin oxide alone, even approximately. Furthermore in the case of some alloys it is practically impossible to render the tin oxide insoluble by merely evaporating the solution to dryness. The determination of tin by conversion into oxide of the stannic sulphide precipitated in Group II. after electrolysis of the copper in sulphuric acid solution, has been found to give results which are satisfactory but very slightly high. Under the conditions of acidity prevailing in our method of analysis, no tin sulphate is found to hydrolyse out with the silica, nor is any tin deposited with the copper during electrolysis.

The methods here described are those which we have found to be most generally useful. The reagents required are (a) a 10% solution of pure sodium hydroxide, (b) nitro-sulphuric acid made by mixing 300 c.c. of concentrated sulphuric acid with 300 c.c. of water, cooling, and adding 200 c.c. of pure nitric acid (sp. gr. 1.42).

METHOD 1. For unalloyed aluminium and for alloys with low zinc (type 2).

Lead. Two grms. of the metallic drillings is weighed out into a 300 c.c. tall beaker, covered with about 70 c.c. of 10% sodium hydroxide solution, and allowed to dissolve till evolution of gas practically ceases. The caustic soda solution is then decanted off through a prepared Gooch crucible and the insoluble portion washed with water. It is then dissolved in a little nitric acid and the solution evaporated to fuming with 10 c.c. of concentrated sulphuric acid on a hot plate. When cool, the liquid is diluted to about 50 c.c. with water and allowed to stand until the lead sulphate and some silica have separated completely. The precipitate is filtered off on a Gooch crucible and washed with dilute (1 in 6) sulphuric acid. The contents of the Gooch crucible containing the lead sulphate (and silica) are extracted with hot 30% ammonium acetate solution; the extract is acidified with hydrochloric acid, and the lead removed as sulphide by passing hydrogen sulphide

through the solution. The sulphide is filtered off, dissolved in nitric acid, evaporated with a small quantity of sulphuric acid, and estimated as lead sulphate in the ordinary way. If there is not much silica with the lead sulphate, as generally happens, it is accurate to ignite the mixture on the Gooch crucible to a dull red heat, cool, weigh, extract with hot 30% ammonium acetate, ignite the crucible, and take the loss in weight as lead sulphate.

Manganese. The filtrate from the first precipitate of lead sulphate is treated with about 20 c.c. of strong nitric acid, cooled, and oxidised with sodium bismuthate in the cold. In this way, the presence or absence of manganese is determined. If the colour of the permanganic acid indicates only a few hundredths per cent. of manganese, the solution is filtered through a Gooch crucible packed with asbestos and titrated with N/20 ferrous ammonium sulphate in the usual way. Should the manganese exceed 0.1% it is best to determine it on another portion, since if present in more than slight traces, it tends to dissolve in the soda. For an accurate estimation of manganese 1.1 grms. of alloy is treated with 30 c.c. of 10% soda as above till evolution of gas ceases, and nitric acid added till the solution is acid and all the metal has dissolved. Then another 20 c.c. of concentrated nitric acid is added, the solution is boiled and cooled, and the manganese determined after oxidation with bismuthate.

Main analysis. While the lead estimation is being carried out, the main analysis is started. One gm. of the metal drillings, preferably not too fine, is weighed out into a 400 c.c. tall beaker without a lip. 10 c.c. of the nitro-sulphuric acid solution is added and the beaker covered with a well-fitting clock glass. The dissolution of the metal is started by placing the beaker on the hot plate. When the action has begun the beaker is removed from the plate and reaction allowed to proceed. The action becomes rather violent and then subsides somewhat. At this stage a further 15 c.c. of the nitro-sulphuric acid is added and the dissolution is allowed to proceed fairly rapidly, keeping the beaker well covered and warning if the action shows signs of slackening. The last pieces of metal are brought into solution by gently boiling the liquid. During this part of the operation the boiling should not be so vigorous as to remove all the nitrous fumes from the beaker. When solution is complete, the cover glass is moved slightly to one side of the beaker and evaporation continued fairly rapidly until most of the water and nitric acid has been expelled. The cover glass is then removed and the evaporation continued without boiling until fumes of sulphuric anhydride form and the liquid begins to become turbid. At this point a clean glass rod is introduced and the liquid is stirred, the beaker being moved about on the plate at the same time, to avoid superheating at any point and prevent bumping. When the contents are nearly solid, the beaker is removed from the hot plate and the stirring continued in order to break up the cake of sulphates and ensure complete solidification. The beaker is then replaced on the hot plate and allowed to fume for a few minutes to render silica insoluble, after which it is taken off, covered with its original cover glass, and allowed to cool.

The dissolution and evaporation are not so difficult to carry out as might at first appear. With a little practice the exact time to begin the stirring can easily be recognised. If stirred too early the mass will not solidify quickly, but will show a great tendency to bump, while if evaporation is carried too far, the mass grows solid very suddenly and bumps violently. The condition to be aimed at is a certain degree of super-saturation before stir-

ring. Four samples may be dissolved and evaporated to this stage in half an hour.

Silicon. When the beaker has cooled somewhat the cover glass and sides of the beaker are washed down with water and the mixed sulphates are stirred to a paste. About 60 c.c. of water is added altogether, and the sulphates are then dissolved by boiling for a few minutes on the hot plate. The solution is filtered through an ashless filter into a 250 c.c. squat beaker and the silica and silicon (together with some lead sulphate, if any lead is present in the alloy) on the filter are washed several times with hot water. The precipitate is ignited *gently* in a platinum crucible and weighed. The silica is volatilised (a) by means of a few drops of hydrofluoric acid and sulphuric acid, and the residue is ignited and weighed, the loss of silica being calculated to silicon. If the contents of the crucible indicate silicon, generally in the form of a black coating near the bottom of the crucible, the residue is treated with a few drops of hydrofluoric acid, nitric acid, and sulphuric acid, evaporated to dryness, again ignited, and weighed. This second loss is taken as silicon and the result added to the silicon first volatilised at (a) as silica. If the metal contains much lead the ignition of the silicon, silica, and lead sulphate should of course be conducted very carefully, not only to prevent damage to the crucible, but to avoid any possible conversion of the lead sulphate and silica into lead silicate.

Copper. To the filtrate from the silica, etc., in the 250 c.c. squat beaker 25 c.c. of nitric acid (sp. gr. 1.42) is added and the solution subjected to electrolysis, using a rotating cathode consisting of a weighed platinum gauze about 25 cm. in diameter and 3 cm. long, and a plain platinum disc about one inch square for anode. We use a current of 2–3 amperes. When the copper has been removed, *i.e.*, the solution has become colourless, the sides of the beaker and the cover are washed down with a little distilled water and electrolysis continued for another ten minutes. The cathode is then removed as quickly as possible and washed, the wash water falling into the beaker used in the electrolysis. It is then dipped in clean alcohol, dried in the steam oven and weighed, the weight of the copper deposit giving the copper content of the metal. Any lead or manganese oxides on the anode are also gently washed with water to avoid any loss of solution, but the deposit on the anode is rejected. It is not needed further, because lead and manganese have been separately determined as above.

Tin. The solution after electrolysis is saturated with hydrogen sulphide. The character of the precipitate reveals the presence or absence of tin. The precipitate is filtered off, catching the filtrate in a 400 c.c. tall beaker, and washed with acidified hydrogen sulphide water containing a little ammonium nitrate. If tin is absent the precipitate is ignited and the copper in it estimated by dissolving in a little strong nitric acid, adding excess of ammonia, and matching the blue colour produced by means of a standard copper solution containing one gm. of copper per litre. The "copper traces" thus estimated should not exceed 0.05%, corresponding to 0.5 c.c. of the standard copper solution. If tin is present, the precipitate, after washing as above, is extracted on the filter with a warm dilute sodium sulphide solution to remove the tin sulphide, and the small residue of black copper and lead sulphides washed with a little hot water. This residue is then ignited and the "copper traces" determined colorimetrically, the result being added to the copper determined electrolytically. The solution of sodium thioannate is acidified carefully with hydrochloric acid, saturated with hydrogen sulphide, and allowed to stand on the steam bath to

settle. The tin sulphide is filtered off and washed with slightly acid ammonium nitrate solution until free from chlorides. It is then transferred from the filter to a weighed porcelain crucible 4.5 cm. in diameter (wide form) and treated with about 1 c.c. of nitric acid (sp. gr. 1.42), and the mass evaporated to dryness on the steam bath. The residue is then ignited gently to burn the charred filter, and finally strongly, to convert it into tin dioxide, in which form it is weighed. It is found that a part of the "copper trace" is often dissolved by the sodium sulphide owing to the formation of polysulphide with the sulphur in the precipitate, but this copper which contaminates the tin oxide is easily determined colorimetrically as above, the object of the sodium sulphide treatment being to free the tin sulphide from lead sulphide, which remains wholly undissolved. If lead has been proved to be absent, the sodium sulphide treatment may be dispensed with.

To the filtrate from Group II. sulphides, 7 grms. of pure tartaric acid is added; the solution is then made alkaline with ammonia, and about 10 c.c. of ammonium sulphide solution introduced. The beaker is covered, and the precipitate allowed to settle on the steam bath. If nickel is absent from the metal, the precipitate consisting of zinc, iron, and manganese sulphides is filtered off and washed till free from tartaric acid, with an ammonium nitrate solution containing a little ammonium sulphide.

Iron. The mixed sulphides are dissolved in hot dilute hydrochloric acid, oxidised with bromine, and the iron and manganese precipitated from the solution by bromine and ammonia. A double precipitation is of course necessary. After this, a basic acetate separation should be carried out to separate the iron and manganese from one another, and then the basic iron acetate dissolved and reprecipitated from ammoniacal tartrate solution with ammonium sulphide. The ferrous sulphide thus obtained is ignited and weighed as ferric oxide.

Zinc. The solution containing the zinc should be rendered faintly acid with hydrochloric acid, and some ammonium chloride and about one gm. of microcosmic salt added to precipitate the zinc as zinc ammonium phosphate, which is filtered off, washed with water, ignited to zinc pyrophosphate, and weighed. If, however, the zinc is less than 1%, we consider it preferable to precipitate the solution with ammonium sulphide, filter off the zinc sulphide, ignite at the lowest possible temperature, and weigh as zinc oxide.

Magnesium. To the filtrate from the zinc and iron sulphides a solution containing 5 grms. of microcosmic salt is added, with vigorous stirring; ammonia is then added, with further stirring. The solution is then allowed to stand, preferably overnight, to precipitate any magnesium as magnesium ammonium phosphate. The precipitate is filtered off, redissolved in a little dilute hydrochloric acid, a little tartaric acid and microcosmic salt are added, and the magnesium reprecipitated by gradually adding ammonia and stirring; then ammonia in excess is introduced and the liquid put aside for about 2 hours, after which the precipitate is filtered off, ignited to magnesium pyrophosphate, and weighed as such.

It should be noted, however, that in this process, manganese if present to any extent is liable to contaminate the magnesium, and possibly the zinc precipitate. If this is found to be the case the manganese content of each ignited precipitate is determined by means of sodium bismuthate, and the necessary correction applied after calculating to $Mn_2P_2O_7$ in the case of phosphate precipitates, or Mn_2O_3 in the case of the zinc oxide precipitate.

If the alloy contains nickel, the procedure must be modified somewhat. Part of the nickel sulphide is precipitated with the alkaline sulphides, *i.e.*,

with the iron, zinc, and manganese, and to dissolve the precipitate completely, a little nitric acid as well as hydrochloric acid must be poured over the filter. The iron and manganese are separated from the zinc and nickel as before, with bromine and ammonia, and the nickel is separated from the zinc by means of 1% alcoholic dimethylglyoxime, in slightly ammoniacal solution. The nickel precipitate is filtered off, washed, and discarded, and the zinc determined as above. The other portion of the nickel will be found in the filtrate from the mixed alkaline sulphides. This is acidified faintly with acetic acid, hydrogen sulphide is boiled off, and a little dimethylglyoxime added to the solution, which is rendered faintly alkaline with ammonia and allowed to stand in a warm place for about 20 minutes. The precipitate of sulphur, nickel sulphide, and nickel dimethylglyoxime is filtered off and discarded. The filtrate is then made alkaline with about 20 c.c. of strong ammonia, and 5 grms. of microcosmic salt added as before in order to obtain the magnesium.

Nickel. The nickel is best determined on one gm. of the alloy by dissolving out the bulk of the aluminium and zinc with 40 c.c. of 10% soda, filtering off the insoluble metallic residue, and dissolving this in nitric acid. Group II. metals are removed by means of hydrogen sulphide, the excess of which is expelled by boiling. Four grms. of tartaric acid is then added to the solution, which is heated to 60° C., and an excess of dimethylglyoxime (1% alcoholic solution) added, followed by sufficient ammonia to render the liquid slightly alkaline. The precipitated nickel dimethylglyoxime is filtered off on a freshly prepared Gooch crucible packed with asbestos, washed with hot water, dried to constant weight in the steam oven, and the nickel estimated on the assumption that the precipitate contains 20.32% of nickel.

The whole process described above may appear lengthy, but it must be remembered that manganese and nickel are absent in the majority of cases, while magnesium is only present in traces except in special alloys; so that the time required for the analysis is considerably shortened. Nevertheless, the scheme is designed to cover all the metals likely to be found in types (1) and (2), and after going through the process it is quite safe to take aluminium by difference, as is usually done.

The method is applicable to every type of aluminium metal and the results are accurate. The chief difficulty, however, arises with metals containing a large proportion of zinc (type 3). In this case, the method occupies 16 to 20 hours. The reason for this is the time taken in the settling, filtration, and washing of the mixed sulphides of iron and zinc. If plenty of iron is present, the mixed sulphide does not filter badly, but it is slow work at best; while, if the iron content is low and the precipitate of a light grey colour it is most difficult to retain it on the filter during washing. The time required to filter and wash such a precipitate satisfactorily is about four hours.

We have therefore devised another method for alloys containing much zinc. Titration methods were not very promising and electrolytic methods were therefore resorted to. The only electrolyte that appeared suitable for the separation of aluminium and zinc was alkali hydroxide, containing aluminate and zincate. From such a solution, using a rotating cathode, it was found possible to precipitate about 0.2 gm. of zinc free from aluminium and only leave traces of zinc—less than a milligram—in the solution. Sulphates in the solution did not interfere with the zinc electrolysis, but nitrates or ammonium salts prevented the deposition. In applying this method to aluminium alloys, various difficulties were at first encountered. As nitrates or substances likely

to generate ammonia must be excluded, the addition of 25 c.c. of nitric acid to the solution as recommended above for types (1) and (2), before electrolysis of copper is inadmissible. The first trials for the complete analysis of aluminium alloys using the electrolytic method for zinc involved the removal of all Group II. metals by hydrogen sulphide. Another difficulty was the estimation of the iron. This was finally accomplished by boiling off the hydrogen sulphide after removing Group II. metals, oxidising the solution with a little bromine water, adding about one gm. of tartaric acid and then excess of sodium hydroxide solution. Under these conditions the iron, aluminium, and zinc remain in solution, and when the liquid is subjected to electrolysis, the iron and zinc are deposited together as a clean layer. Magnesium has no deleterious effect, although in this case the electrolysis is carried out with magnesium hydroxide suspended in the liquid. Quantities of magnesium up to 1% do not contaminate the zinc deposit. Manganese, however, shows a decided, and nickel a slight, tendency to be deposited with the zinc. These metals rarely occur in alloys of type (3), however, and even if the deposit is contaminated with them, the degree of contamination can easily be determined as shown below, and the necessary corrections applied. The iron-zinc deposit can be dissolved off the cathode in dilute sulphuric acid and the ferrous iron titrated with $N/20$ permanganate.

Numerous experiments were made in order to find the most suitable cathode for the zinc electrolysis. Platinum cannot be used as the surface is permanently spoiled by the zinc, while the use of copper makes it impossible to determine the iron by titration after dissolving the iron-zinc deposit in dilute sulphuric acid. A silver cathode overcomes this last difficulty, but the electrode retains a little of the zinc and cannot be ignited before use. Finally, a gold plated platinum electrode was used; this was in the form of the platinum gauze cylinder, 25 cm. in diameter and 3 cm. long, used for the copper electrolysis and upon which a coating of about 0.1 gm. of gold was deposited from a cyanide solution. The coating extended for about 1 cm. up the axial stem, i.e. above the top of the gauze. The iron-zinc deposit dissolves off this cathode more completely than off the other metallic electrodes, and seldom leaves more than 2 mgrms. of zinc, in which no iron can be detected. The electrode, after cleaning in dilute sulphuric acid, is slightly dark, but can be completely freed from the last traces of adherent zinc by immersing in hot nitric acid (sp. gr. 1.2) for a short time. Before use, these gilded electrodes are gently ignited and then weighed. They have proved very satisfactory in use.

In the course of investigations into the electrolysis of copper from sulphuric acid solutions containing no nitrates, or urea or other substances likely to generate ammonia during the subsequent zinc electrolysis, it was found that the copper deposit was of a dark brown or black colour and the result was generally about 0.1% higher than if nitric acid were present in the solution. It was noticed, however, that the blackening of the deposit only occurred at those parts of the cathode that were wholly immersed in the solution during the revolution of the cathode. The portion of the copper deposited on the upper part of the cathode, which was partly out of the solution during its rotation, remained bright. This led us to think that the atmospheric oxygen was keeping the deposit bright, and an experiment was performed with the anode placed beneath the rotating cathode to observe the effect of the anodic oxygen on the deposit. The result was that the copper deposit was bright at the top of the cathode, black in the middle, and dull red at the bottom, showing clearly that a mild oxidising agent was necessary to keep

the deposit bright. Moreover, as it was found that a trace of sulphur dioxide or a small crystal of sodium sulphite added to the solution greatly intensified the blackening of the copper, sometimes with the deposition of sulphur in the solution, it was concluded that the blackening of the copper and the high results during electrolysis in pure dilute sulphuric acid were due to the reduction of sulphuric acid and the deposition of a film of copper sulphide. After various trials, hydrogen peroxide was found to be the most suitable oxidising agent to use in order to get a bright copper deposit and at the same time avoid the presence of nitrates. With hydrogen peroxide the copper remains bright unless the time of electrolysis is prolonged unduly beyond that required for complete deposition of the copper. When the copper has all been deposited, the cathode hydrogen begins to reduce the hydrogen peroxide, and as soon as this is all destroyed, the solution becomes full of gas bubbles. There is then the usual tendency for the copper deposit to blacken. If this free evolution of gas is observed, the copper can be kept bright by the further addition of one or two c.c. of hydrogen peroxide solution.

Method II. The observations recorded above enabled us to devise a new and rapid method for the analysis of aluminium alloys, especially those with high zinc content. The process is as follows:—

Lead and manganese. Two grms. of the metal is treated with caustic soda and the residual metals examined for lead and manganese as described in the first method above.

Nickel and magnesium. One gram. of the metal is treated with 10% sodium hydroxide solution till action ceases, the insoluble metals are filtered off, and dissolved in nitric acid. Group II. metals are removed by hydrogen sulphide, the excess of which is boiled off. The nickel, if present, is precipitated from an ammoniacal tartrate solution by means of dimethylglyoxime, and is filtered off on a Gooch crucible and weighed. The filtrate from the nickel is precipitated with ammonium sulphide and any iron and zinc sulphides filtered off and rejected. The filtrate from the zinc sulphide is examined for magnesium, by adding microcosmic salt, as in the general method already described. Generally nickel is absent, and magnesium is not present except as traces.

Main analysis. One gram. of the metal is dissolved, as described in the general method above, in nitro-sulphuric acid and the silica and silicon filtered off. To the filtrate, occupying about 100 c.c. in volume, 7 c.c. of "20-volume" pure hydrogen peroxide is added, the liquid is well mixed, and the cool solution subjected to electrolysis, using the rotating gauze cathode previously referred to and a current of 2 ampères. Electrolysis is continued for 10 minutes after the solution becomes colourless, adding a little more hydrogen peroxide if necessary, to prevent evolution of gas. The cathode is washed down with distilled water, dipped in clean alcohol, dried at 100° C., and weighed. The liquid is saturated with hydrogen sulphide, filtered into a 400 c.c. squat beaker, and the sulphide precipitate carefully washed with warm water (ammonium nitrate solution must not be used), and then examined for traces of copper and for tin, by the method already described. The filtrate from the Group II. sulphides is now boiled to expel hydrogen sulphide, and a little bromine water added to oxidise any sulphur and ferrous iron. The solution is cooled, about one gram. of pure tartaric acid is added, followed by a 50% solution of pure sodium hydroxide,* until the

alumina and zinc oxide at first precipitated have just redissolved. A further 20 c.c. of the 50% soda solution is added, the solution cooled to room temperature and made up to about 300 c.c. If the concentration is too great or the temperature too low, salts tend to crystallise out. At this stage magnesium hydroxide is precipitated and this forms a delicate test for minute quantities of magnesium in the alloy, since 1 mgrm. shows readily. The liquid is electrolysed, using the weighed gilt platinum rotating cathode, for half-an-hour with a current of 1.7 ampères (3 to 4 volts), then for half-an-hour at 2 ampères. Under these conditions the solution does not become very warm, and if the electrode is well immersed in the electrolyte, the deposit is of a light bluish grey colour with a small dark ring round the stem where the latter enters the solution. At the end of an hour the cathode is quickly washed with several changes of distilled water, dipped in alcohol, dried in the steam oven, and weighed. The weight of the deposit gives the total iron and zinc, together with a little nickel and manganese if these are present in the original metal. To analyse the deposit, the cathode is immersed in warm 30% sulphuric acid, the deposit dissolved off, and the clean cathode removed. If the alloy contains no manganese the resulting solution is titrated with N/20 potassium permanganate solution and the weight of iron in the deposit obtained. On the other hand, if manganese is present, the cathode solution is divided into two portions, the ferrous iron being titrated with N/20 potassium permanganate in one part, and the manganese determined in the other by addition of nitric acid, cooling, oxidising with sodium bismuthate to permanganic acid, and titrating with N/20 ferrous salt solution as usual. If the metal contains nickel, the portion of the cathode solution used for the iron titration is treated with about a gram. of tartaric acid, a few c.c. of dimethylglyoxime solution are added, and the solution made faintly alkaline with ammonia. The nickel dimethylglyoxime precipitate is filtered off, dried, and weighed, and the nickel on the cathode is thus obtained. The true weight of zinc in the cathode deposit is obtained by subtracting the combined weight of iron, nickel, and manganese from the weight of the deposit. We find, however, that nickel and manganese are very rarely present in the cathode deposit.

The alkaline solution left after the zinc-iron electrolysis is treated with a few c.c. of sodium sulphide solution, when traces of iron and zinc which may not have been deposited, soon show as sulphide. Should the sulphide precipitate amount to more than traces, it is filtered off, redissolved in dilute hydrochloric acid, and the iron and zinc separated and weighed. In most cases, however, the amount of zinc and iron not electrolysed is extremely small, much less than 0.1%. This is especially the case if the zinc is largely in excess of the iron, as is usual with metals of type 3, where the iron seldom exceeds 1% and the zinc is generally 9% or more. Recently, however, the authors have tried to apply the method to metals of type 2, when zinc is present as a constituent. In the majority of cases the electrolysis has succeeded in removing practically all the iron and zinc from the solution. Sometimes, however, from some unknown cause, the method fails with these alloys. The cathode becomes coated with a deposit containing a little zinc and all the iron, after which no further deposit of zinc can be obtained, but the rest of the zinc can be deposited on a fresh cathode. Alternatively the remainder of the zinc in this case may be precipitated by means of sodium sulphide.

So far as accuracy is concerned the processes here described leave little to be desired. The copper

* Certain samples of "pure" sodium hydroxide have been found to contain a little zinc.

determined by electrolysis in the presence of hydrogen peroxide has been generally found to agree exactly with the results obtained with nitric acid in the solution and seldom differ by more than $\pm 0.03\%$ on a 3% copper content. With reference to the iron-zinc determination, we consider that the results are better than those obtained by the ordinary separation of iron and zinc. The cathode deposit is almost identical in weight with the combined weight of iron and zinc determined by the method given for metals of type 2, but after carrying out the permanganate titration for the iron in the cathode deposit, the percentage of zinc is slightly higher, and of the iron slightly lower (generally of the order 0.05–0.1%) than that obtained by the usual chemical separation and weighing. This may be due partly to the great difficulty of separating zinc completely from iron by chemical means, as is made plain by Withey's experiments (*loc. cit.*), or it may be due to slight oxidation of the ferrous iron during solution of the cathode deposit. To test this latter point 0.1718 gm. of pure zinc oxide, corresponding to 0.1380 gm. of zinc, was dissolved in dilute sulphuric acid, and 20 c.c. of a ferrous sulphate solution (containing 0.0101 gm. of iron per 20 c.c., as determined by reduction with sulphur dioxide, boiling off excess gas, and titrating with $N/20$ permanganate) was added. After oxidation of the iron with bromine and making the solution to correct strength with tartaric acid and caustic soda, the iron and zinc were deposited by electrolysis. The deposit weighed 0.1486 gm. and the weight of iron, as determined by dissolving off in dilute sulphuric acid and titration with $N/20$ potassium permanganate, was 0.0102 gm., leaving 0.1384 gm. as the weight of the zinc deposit. These figures, which are typical of many results, confirm the accuracy of the method of estimation. Moreover, when duplicate analyses of an alloy have been carried out, the combined weight of zinc and iron in the two cases has been found to be within 0.5 mgrm. on deposits weighing about 0.13 gm. Where the iron content has been determined in one deposit after solution in sulphuric acid by titration with standard permanganate, and in the other by precipitating the iron once as hydroxide from ammonia and ammonium chloride solution, twice as basic acetate, and once again as hydroxide, as recommended by Withey (*loc. cit.*), the two iron results are found to be in very close agreement.

We have made a number of experiments to determine the completeness of the precipitation of magnesium in the presence of zinc and aluminium by means of sodium hydroxide and tartrate, and find that as little as 1 mgrm. of magnesium is wholly precipitated under the conditions described above. The magnesium hydroxide may be filtered off before or after the electrolysis of the zinc solution, redissolved, and reprecipitated as magnesium ammonium phosphate from an ammoniacal tartrate solution. In the absence of nickel this method of determining magnesium is accurate.

We desire to express our indebtedness to Sir J. J. Dobbie, F.R.S., for permission to publish the methods and results in this paper.

DISCUSSION.

Mr. C. E. BARRS agreed with the authors that lead was often present in aluminium, more particularly so if the alloy contained zinc. The suggestion to use a platinum electrode coated with gold led him to inquire why a gold electrode could not be used and so save the expensive platinum. He also asked whether the authors had made any experiments on the direct estimation of aluminium.

Dr. R. SELIGMAN said that the specifications to which they were required to work nowadays demanded the absence of appreciable quantities of lead in alloys of the type under discussion, and

it therefore could not be assumed that the alloys would be free from this material. On the contrary, the vast majority of alloys which were made up with ordinary spelter contained the proportion of lead which the spelter carried, and it was only alloys which were made up from modern electrolytic zinc which were free from lead. It was, therefore, essential that these alloys should be tested for lead.

Dr. Fox, replying to the discussion, agreed with Dr. Seligman's remarks. A gold electrode could, of course, be used but platinum was more rigid. He knew of no short method for the direct estimation of aluminium; the only procedure was to estimate it in the usual way by going through the separations. The result was usually 0.3% or 0.4% too high.

Newcastle Section.

Meeting held at Bolbee Hall on November 20th, 1918.

PROFESSOR P. PHILLIPS BEDSON IN THE CHAIR.

THE RELATION BETWEEN MOLECULAR STRUCTURE AND THE ACTIVITY TOWARDS HYDROGEN SULPHIDE OF OXIDE OF IRON.

BY G. WEYMAN.

In recent years almost the whole of the purification of coal gas from hydrogen sulphide has been effected by oxide of iron. The sulphides of iron with which such purification is concerned are the sesquisulphide, Fe_2S_3 , which is oxidised by atmospheric air to free sulphur and ferric oxide; the monosulphide, FeS , which is also oxidised to free sulphur and ferric oxide, and which at higher temperatures may combine with free sulphur to form the disulphide, FeS_2 . It seems somewhat uncertain whether the disulphide when prepared in this way will further oxidise in air to give ferrous sulphate. Ferrous sulphate, however, is always present in the unoxidised sulphides, although at low temperatures the amount may be small. After oxidation the amount is certainly increased.

Purification of coal gas is carried on at temperatures somewhat above the normal, under which conditions the sesquisulphide is the chief product. L. T. Wright (J. Chem. Soc., 1883, 156) found that by treating the hydrate precipitated by ammonia from ferric chloride with hydrogen sulphide and treating the product with carbon bisulphide out of contact with the air, a variable amount of free sulphur was produced, which bore no relation to the total quantity of free sulphur obtained after oxidation.

Free sulphur is always present from one source or another, and disulphide is produced by local heating. Subsequent oxidation might account for part of the ferrous sulphate found. This reaction also results in the liberation of sulphur dioxide. In those cases where there is no excess of alkali present the oxide quickly becomes acid, and the activity falls off with remarkable abruptness. If the oxide is maintained in an alkaline condition, the ferrous sulphate formed is immediately decomposed, with the result that the full amount of ferric hydrate is liberated, and available for further use. Even in an alkaline condition the activity of the oxide falls off in course of time. In an acid condition the amount of iron rendered inert by the formation of ferric and ferrous salts, or as the disulphide, is not sufficient to account for the almost complete inactivity of the whole body of the oxide.

Gedel* has pointed out the remarkable influence of traces of ammonia or acid on the absorption of hydrogen sulphide by oxide of iron, and has found that in the latter case the monosulphide (and later the disulphide) was formed; in the former case only the sesquisulphide. He could not find any monosulphide in ordinary works oxide, a fact he attributed to the presence of ammonia.

Although Lewis Thompson, in his "Chemistry of Gas Lighting," states that the activity of iron oxide depends on molecular structure rather than on hydration, it is generally considered that only hydrated oxide is active, probably owing to the fact that strongly ignited oxide is certainly inactive.

In order to determine the precise temperature at which hydrated oxide became inactive, differently prepared pure samples were heated in an open silica tube to various temperatures measured by a thermocouple inserted in the oxide, for two to three hours, and then cooled and examined for their absorptive power towards hydrogen sulphide. The latter operation consisted in passing dry hydrogen sulphide over a weighed quantity of the oxide in a weighed tube of which the outlet was connected to a weighed calcium chloride tube. The air was displaced before and after the experiment by dry carbon dioxide. Three hours was given for the absorption, by which time it was practically complete. No additional water was added in any case.

In all cases, except one, the oxide obtained after heating to 100°, 300°, 350°, 400°, 450°, 500°, 550°, 600°, and 650° C. gave in the cold practically theoretical absorption (62.63%, theoretical = 63.7%) calculated on the content of ferric oxide. The oxide obtained by heating to 650° C. did not turn black till 5 minutes after the hydrogen sulphide was passing at the outlet; it then became black suddenly, with considerable heat effect. Oxide heated to 700° C. only gave a partial absorption, the extent of which depended on the time of heating and ranged from 10% to 32% of hydrogen sulphide. The oxide heated to 800° C. absorbed less than 1%. In the exception noted above, the hydrate dealt with was obtained by precipitation of a fresh solution of ferric chloride by ammonia, and drying at 100° C. Dried at this temperature it had the maximum activity, but when heated to 250° C., just after losing the bulk of the water, it became incandescent, and left on cooling a black, lustrous, hard residue which was inactive. On further heating the colour changed to puce, but the oxide was still inactive. In all cases most, at any rate, of the water of hydration was given off below 300° C.

It is evident then that ferric hydrates dehydrated at as high a temperature as 650° C. may still retain their activity in the cold. At about 700° C. a change sets in which may also be effected at lower temperatures by very prolonged heating. The sulphide formed in the above cases was entirely ferric sulphide, and oxidised in air with sufficient rapidity to set fire to the liberated sulphur. A determination of the free sulphur in one case in the unoxidised sulphide gave only a trace of sulphur when the quantity taken was 10 grams. This shows that under certain conditions, and with particular varieties of oxide, the absorption of hydrogen sulphide may take place in the comparative absence of water in accordance with the equation $\text{Fe}_2\text{O}_3 + 3\text{H}_2\text{S} = \text{Fe}_2\text{S}_3 + 3\text{H}_2\text{O}$.

The absorptions noted above were made at atmospheric temperature, but if the oxide is treated with hydrogen sulphide at higher temperatures the reaction takes a different course. In this case, the sulphide or sulphides formed are only attacked

by dilute acid when heated to boiling point, and then liberate hydrogen sulphide. No ferric oxide is formed on oxidation but only ferrous sulphate; the latter compound is also present in the unoxidised powder.

Even the oxide heated to 800° C. and which was inactive in the cold absorbed the gas with avidity at the higher temperatures. This indicated that the change in structure which inhibits the action of hydrogen sulphide in the cold must take place on cooling, and that at 800° C. the oxide molecules are in such a mobile state that slow cooling gives them an opportunity of arranging themselves in a more condensed state. To obtain further evidence of this, some oxide was heated for three hours to 800° C. and all but a check portion was plunged suddenly into cold water. The check sample, which was cooled slowly, absorbed less than 1% of hydrogen sulphide in the cold, while after drying the quickly cooled sample absorbed 43%. With a better cooling arrangement it would seem probable that the absorption would be more nearly theoretical.

An attempt to demonstrate a heat effect by cooling and heating curves failed.

The specific gravities of the powders obtained by heating to various temperatures and cooling slowly were determined in pure toluene. They showed a progressive rise; for instance after heating to 300° C. sp. gr. = 4.207; to 510° C., 4.444; to 700° C., 4.485.

To avoid possible confusion it might be mentioned here that "burnt oxide" from the manufacture of sulphuric acid is in a similar condition to the oxide heated above 700° C. It has been and is used for gas purification—not so much on account of the ferric oxide, as by reason of a varying content of ferrous sulphate, which is converted into ferric hydrate by addition of an alkali and subsequent oxidation before use. Unfortunately the burning of the material is often carried to such a point that little or no ferrous sulphate is left, and the material is worthless from this point of view. It is true also that the amount of ferrous sulphate necessary to make it of value is relatively small because with revivification *in situ*, which is now universally the practice, the same oxide may be alternately fouled and oxidised many more times than used to be commercially feasible.

The above considerations lead to the idea that the chemical activity of iron oxide is dependent primarily on molecular structure, and not on any particular degree of hydration. At the same time the molecular structure is evidently derived in almost all cases from some form of hydrate.

Passing, then, to the question of the constitution of the ferric hydrates, I hope to show that the conclusions arrived at by former investigators admit of a very close application and find some confirmation in the study of gas purification.

Péan de St. Gilles,* studying the action of boiling water on hydrated ferric oxide, found what he considered to be a soluble modification. Graham, later, subjected solutions of ferric salts to dialysis and succeeded in getting a similar result, namely a solution containing very little else except ferric oxide. Magnier de la Source and others prepared solutions containing even less of the acid radicle, but still a small quantity was invariably left. Bechamp,† after pursuing the matter still further and taking into consideration the facility with which ferric oxide dissolves in ferric chloride, decided that there were formed true compounds of ferric oxide and hydrochloric acid of a more condensed type, which he considered were basic oxychlorides. Lewis T. Wright,‡ in preparing

* Ann. Chim. et Phys., 1856, [3], 46, 47.

† Ann. Chim. et Phys., 1859 [3], 57, 296.

‡ Loc. cit.

ferric hydroxide in order to study the action of hydrogen sulphide upon it, noticed the difficulty of getting the precipitate free from chloride, and found that after washing practically free from chloride a further quantity was obtained after drying; moreover, under certain conditions, the ferric oxide became so finely divided that it passed through all filter papers but yet was not in true solution. Wright observed the different colours of ferric hydrate prepared in different ways, and quotes Tommasi,* who obtained a soluble modification by keeping ferric hydrate (presumably containing some chloride) under water for a year. Tommasi also found that at the same time 30% of his sample was insoluble in dilute acid, some was unaffected by hydrogen sulphide, and some again was only altered by this gas after ten minutes' contact when it suddenly "flashed black." Wright suggested that the soluble modifications were only basic salts, and states that ferric hydrate when washed and dried at 100° C. becomes converted into an inactive form. Further, by treatment of the hydrate suspended in water with hydrogen sulphide and subsequently dissolving out the sulphide with potassium cyanide, Wright was able to estimate the proportion of the two types. The study by Wyrouboff and Verneuil† of the oxides of the rare earths and the subsequent application of their results by Nicolardot‡ to the ferric hydrates shed a new light on the matter.

Nicolardot pointed out that the solutions of the ferric hydrates in ferric chloride are strongly acid and decompose carbonates. They can therefore hardly be basic chlorides. He succeeded in preparing a number of the compounds and in drying them over sulphuric acid to constant weight, in spite of the fact that Van Bemmelen did not thus succeed, and proved instead by the vapour pressure curves that no definite hydrates could exist. Van Bemmelen, however, was working with a mixture of very similar substances, each of which there seems no reason to doubt would be quite definite if it could be isolated.

Nicolardot, after careful and persistent working, showed that the substance precipitated from ferric solutions may vary very largely according to the conditions, such as the freshness of the ferric solutions, the temperature, and the manner of adding the reagents. Such a precipitate contains varying quantities of different polymerised compounds, some more strongly condensed than others, each molecule containing a number of ferric oxide molecules bound together and acting as a unit combining with one equivalent of hydrochloric acid. These compounds may undergo further condensation on heating or simply on standing, and the condensed molecules in some cases may become depolymerised. Hydrates prepared in other ways, such as are formed when solutions of ferrous salts are precipitated by an alkali and allowed to oxidise in air, give other forms with substantially different properties. The condensation changes give well-defined heat effects. In short, the condensed hydrates are considered as derived either from the normal sesquioxide or from two different anhydrides in two different ways. Some are analogous to the pyro and meta acids, being condensed with loss of water, and are of one of the following types: $[\text{Fe}_2(\text{OH})_4]_m - n\text{H}_2\text{O}$; $[\text{Fe}_2\text{O}(\text{OH})_2]_m - n\text{H}_2\text{O}$; $[\text{Fe}_2\text{O}_2(\text{OH})_2]_m - n\text{H}_2\text{O}$. The others are condensed polymers without the elimination of water. They are of the types: $[\text{Fe}_2\text{O}(\text{OH})_4]_p$ and $[\text{Fe}_2\text{O}_2(\text{OH})_2]_p$. Combining with different acids, the first give rise with elimination

of water to complex compounds—ethers, etc. In the latter a monovalent acid group is simply substituted for an hydroxyl group. Only the first and last terms of any series of the compounds are definite compounds. In the first the ratio of ferric oxide to monovalent acid is unity. The intermediate terms are mixtures of the first and last.

Nicolardot further describes six modifications which he isolated and examined, and gives their methods of preparation and properties. This work seems to be of very great importance, for not only is the formation of these condensed products substantiated by his experimental work, but it explains the observations of previous investigators and opens a new phase in the study of the process of gas purification.

The difficulty of freeing ferric hydrate from chlorides meets with an explanation in the formation of acid salts, and the so-called soluble modifications are nothing more than solutions of the salts of very condensed hydrates. Since the hydrates undergo polymerisation so easily and some of the modifications are inactive towards hydrogen sulphide, the trouble found in obtaining anything like a theoretical absorption is clear. The salts of the polymerised hydrates seem to behave with hydrogen sulphide in a similar manner to other iron salts, that is, they will form sulphides provided alkali is present to neutralise the acid set free. Wright's active and inactive oxides are simply different phases of condensation. Moreover, the different phases of condensation would be expected to influence the mode of chemical action, and it is quite possible that one type of compound which is especially susceptible to reduction would give ferrous sulphide on treatment with hydrogen sulphide, while another type would result in ferric sulphide being formed. It is curious that from a solution of a salt the product is uniformly ferrous sulphide. In the purifiers the oxide is, of course, in a solid condition, with, say, 30% of water. If the mass is allowed to become acid, the salt of a polymerised form would be capable of passing into solution, but in an alkaline condition the insoluble hydrate would not do so. Now Gedel found that under acid conditions only ferrous sulphide is formed, while I have pointed out above that when there was no water present and the oxide was neutral only ferric sulphide was produced. On the other hand Wright, working with a hydrate containing some chlorine, but which was dried at 100° C. and contained some water of hydration and was presumably neutral, obtained a mixture of the two sulphides. The acid conditions of Gedel, of course, presupposed that there would be sufficient acid to form a salt of a polymerised base, but not of an unpolymerised base. The action in this case is first one of depolymerisation, followed by reduction and sulphiding. The ferric sulphide would result from depolymerisation and then sulphiding.

The various types of hydrates all seem to approximate to a content of water represented by the formula $\text{Fe}_2\text{O}_3 \cdot \text{H}_2\text{O}$, but vary 1% or so each way. I have never succeeded in drying any form exactly to that composition at 100° C., as Linder did. There is no doubt that changes in molecular condition slowly occur at 100° C., and this must account for the variation.

The behaviour of some of the different types of hydrate has already been dealt with, and it will be noted that they are not the same; in fact the difference in structure prevails at least up to 700° C., at which it seems that there is a tendency of the different types to merge into one another. Nicolardot points out, however, that some give off chlorine and some hydrochloric acid, and that the last traces of water may not be expelled even at 1000° C. At any rate most of the varieties at 700° C. have reached such a state that they cool to an oxide inactive in the cold towards hydrogen sulphide.

* Bull. Soc. Chim., [2], 38, 152.

† Bull. Soc. Chim., 1899, 21, 137; Ann. Chim. et Phys., 1905 [8], 6, 141.

‡ Ann. Chim. et Phys., 1905 [1], 6, 331.

In further study it is evident that precautions should be taken to ascertain the type and degree of polymerisation of the oxide used. The hydrate produced by oxidation of ferric sulphide is not one of the crimson, reddish-brown, or dark brown varieties precipitated by alkalis from solutions of ferric salts; these as a rule become incandescent at about 280° C., and afterwards give a black, inactive, crystalline mass: this hydrate is a yellow or light brown substance similar to that formed by atmospheric oxidation of the hydrates precipitated from solutions of ferrous salts by alkalis. It is fully as active as the red varieties. Consideration of the formation of the natural ores used in gas purification (yellow ochre, bog iron ores, etc.) will show that these have been formed in a similar manner by precipitation under reducing conditions and subsequent oxidation. Further, the red hydrates after the first fouling and oxidation give a similar brownish-yellow type. This transformation seems to be accompanied by liberation of heat, which is added on to the heat of reaction. This means that the absorption is more rapid, but the amount of hydrogen sulphide absorbed in the end is the same.

It is evident, therefore, that gas purification is concerned with these yellow-brown types of hydrates, and it seems to me that further study on these lines will reveal important practical and theoretical results.

In conclusion I must express my gratitude to Mr. F. H. Walker for his help in preparing this paper.

DISCUSSION.

Mr. T. HARDIE said that, in his experience, the difficulties met with in purifying gas by means of natural bog ore were much less than when artificial oxides were used, especially with regard to reduction of efficiency due to acid. When using natural ore it was not difficult to revivify completely *in situ* so that the oxide showed up to 50% sulphur with a single change, whereas with artificial oxide it was difficult to get 50% even with four changes.

Dr. J. T. DUNN remarked on the interesting fact observed by Mr. Weyman that when the oxide was heated to 800° C. and allowed to cool slowly it absorbed practically no hydrogen sulphide, whereas if cooled by dropping into cold water it absorbed 40%. That appeared to be contrary to what one would have expected.

Mr. C. DRU DRURY said that, like Mr. Hardie, he had found considerable differences in the behaviour of the natural and artificial oxides, and his preference was certainly for the former. Artificial oxide was very active in the early stages, but there was considerable difficulty in "fouling up" to sufficient sulphur content in two changes, which they liked to do. The artificial oxide also became very hard and gave back pressure in the purifiers. He asked what percentage of moisture was recommended with artificial oxide to give the greatest activity. It appeared to him that the drier the oxide was, the more active it would be, but it was usual to moisten it slightly to prevent it falling through the grid.

Mr. F. H. WALKER, jun., thought that Mr. Weyman's paper showed the importance of keeping the purifying material in the boxes alkaline. The falling-off of efficiency might be due in the case of artificial oxide to the fact that a small quantity of lime was added to keep the material alkaline; the lime formed calcium sulphate, which caked the mass together, producing the back pressure to which Mr. Drury referred. The observation as to the behaviour of oxide heated to 800° C. and quenched was of very great interest, because, he thought, by that means "burnt oxide" might be made available for gas purification.

Dr. J. H. PATERSON remarked that magnesia heated in an arc furnace and cooled slowly was

inert to certain chemical reagents, whereas if dropped into paraffin and cooled rapidly, it was attacked readily by a number of substances which had no effect upon it in the ordinary condition.

ESTIMATION OF SULPHUR IN SPENT OXIDE.

BY WM. DIAMOND.

The estimation of the amount of sulphur present in spent oxide is customarily carried out by extraction with carbon bisulphide, and upon the figures obtained by this method are based the selling price of the oxide and also the calculation of the efficiency of working sulphuric acid chambers. It is obvious that the results obtained by this process of extraction are misleading, since carbon bisulphide extracts from the spent oxide other impurities, including cyanogen compounds, ammonia, tar, and oil, all of which are weighed and returned as "sulphur."

A method of removing the tarry matter from the oxide before extraction by treatment with sulphuric acid has been suggested, but this appears to be unsatisfactory in several respects. Particulars of a series of experiments on this method of acid treatment have been communicated to me. The results were as follows: Dried spent oxide was heated on a water bath overnight with sulphuric acid of various strengths, up to 40%; the products were not satisfactory. When the pure acid (100%) was used, the product was clean but not entirely satisfactory; also it remained moist, and the subsequent extraction with carbon bisulphide was incomplete. The use of sulphuric acid containing 10% of free SO₂ resulted in the production of sulphur of satisfactory colour. To obviate the difficulty due to the presence of free acid after this treatment, the most satisfactory procedure seems to be to moisten the material, add magnesium oxide, and dry before extraction.

It has been suggested that when oxide is treated with acid, high sulphur figures are obtained owing to the decomposition of thiocyanates, but experiment showed that this was not the case. An attempt was also made to render the tarry matter insoluble by treatment with sulphur dioxide, but the material became so wet that the figures obtained on subsequent extraction with carbon bisulphide were very low.

Proposed method. According to Mendeléeff, sulphur is soluble in carbon bisulphide in practically all proportions, but is only slightly soluble in cold benzene. It occurred to me that by washing dry spent oxide with several portions of benzene, all the tar and oil would be extracted, leaving only the sulphur to be extracted by carbon bisulphide. I therefore had several samples treated in this manner. About 10 grms. of the oxide is placed in an extraction thimble, and nine successive portions of 20 c.c. of cold benzene are poured over the sample, each portion being allowed to filter through the oxide before adding a further portion. A number of tests showed that nine extractions allowed an ample margin. The whole extract is divided into two portions: the first is evaporated to dryness, and the residue weighed; the second is evaporated to dryness, boiled down with nitric acid, water is added, and the sulphur precipitated by barium chloride, and weighed as barium sulphate. The first estimation gives total tar, oil, and soluble sulphur compounds, the second represents the sulphur only; therefore if the second is now necessary to extract the sulphur from the represent tar, oil, and soluble organic matters. It is now necessary to extract the sulphur from the same sample with carbon bisulphide in a Soxhlet extraction apparatus as usual. The weighings will give: 1. Tar, oil, and organic matter soluble in benzene. 2. Sulphur compounds soluble in benzene. 3. Sulphur extracted by carbon bisulphide.

In order that there should not be any dispute as to allocating the soluble sulphur, it is suggested that the proportion thus found be added to the sulphur found by extraction with carbon bisulphide.

In one test of a spent oxide, extraction with benzene gave residues of 14.18 and 13.37% in duplicate tests; the amounts of sulphur found by weighing as barium sulphate were 9.17 and 8.22%; thus the percentages of tar and other soluble matter were 5.01 and 5.14%, average 5.07%. The amounts extracted by carbon bisulphide from the original oxide were 49.87 and 49.79%, average 49.83%; so that the actual sulphur content of the sample was 44.76%.

DISCUSSION.

Dr. J. T. DUNN said that he thought Mr. Diamond was working on the right lines. The plan they had always adopted in his laboratory to determine the sulphur had been, after the extraction by carbon bisulphide, to oxidise a part of the extracted sulphur with nitric acid and determine the sulphate produced as barium sulphate, but his assistant, Mr. Redpath, had some time ago begun work to try to find a solvent that would take out the tarry matters and leave the sulphur. Benzene, as Mr. Diamond had shown, did take out these other substances but it also extracted some of the sulphur. Taking eighteen determinations as to the relative constancy of the proportion of impurity contained in the sulphur extracted, in the highest of these, the pure sulphur formed 98% of the total extracted by carbon bisulphide; the lowest, which was quite exceptional, was 93%, but, in the great bulk of them, the percentage of pure sulphur in the carbon bisulphide extract ranged between 96 and 97% and the average of the whole 18 was 96.4%. From these figures, it would seem that, if the oxide were extracted with carbon bisulphide, and then it was assumed that the total sulphur was 95% of that extract, one would, in nearly all cases, be very near the truth. Still, it would be more satisfactory to have a method of extracting the pure sulphur directly.

Mr. A. TROBRIDGE said that some years ago he had carried on some experiments on the estimation of sulphur by combustion and found that that method gave results which were, on the average 4% lower than by the carbon bisulphide method. He had always considered that the tarry matter led to the use of excessive amounts of sodium nitrate in the sulphuric acid process.

Mr. J. H. WALKER, jun., said that he had found that a considerable amount of sulphur dioxide was produced by roasting the residue after extraction of spent oxide by carbon bisulphide.

The CHAIRMAN remarked that the modifications of sulphur differed very materially in their solubility in carbon bisulphide, some unstable forms not being readily dissolved. The combustion method appeared preferable for the estimation of sulphur in spent oxide.

MR. B. J. SMART IN THE CHAIR.

SOME ADVANTAGES TO BE DERIVED BY THE UTILISATION OF WASTE ON THE SOUTH COAST OF NEW SOUTH WALES.

BY R. W. CHALLINOR.

(ABSTRACT.)

The greater part of the coking industry in New South Wales is concentrated on the South Coast; of the 952 coke ovens in operation in the colony in

1916, 552 are in the South Coast District (Illawarra), 252 in the Northern district (Newcastle, Wallsend, and Singleton) and the remainder in the Western district (Lithgow).

Nearly all the coal is coked in beehive ovens, the only by-product installation being one of 66 ovens at the Broken Hill Proprietary Steel Works. Of the beehive ovens, forty, erected at Corrimal in 1912, are utilising the waste gases under boilers; from the remainder, all the by-products are wasted.

The total production of coke in New South Wales in 1915 was 417,753 tons, of which about 20% was made at the Broken Hill works.

The author pleads for the substitution of modern by-product ovens for the present wasteful beehive ovens, giving figures showing the amounts of the various products which might be recovered. Greig-Smith in 1916 estimated the value of the coke produced in New South Wales in 1913 at £209,000, and that of the by-products which might have been recovered at £344,000. The author, making an independent calculation, estimated the loss of by-products through non-recovery at £1,000,000 in three years.

The installation of by-product coking plant in New South Wales would result in the recovery of ammonia, tar and its products, and render possible the establishment of the manufacture of dyes, synthetic drugs, and perfumes, whilst the coal and coke dust might be saved by briquetting. The waste heat at the South Coast works might be utilised profitably for the evaporation of sea water with a view to producing various salts and bromine. The waste heat from the quenching of the coke should also be utilised. By converting the surplus gas into electrical energy, possibilities are opened up of establishing electro-chemical industries such as the manufacture of alkali, bleaching powder, and chlorinated organic compounds, or of making nitric acid from the atmosphere and ammonium nitrate from this acid and the ammonia recovered from the coking process.

Meeting held at Queen's Hotel, Leeds, on October 21st, 1918.

MR. W. MCB. MACKEY IN THE CHAIR.

SOME ASPECTS OF THE SCIENTIFIC GLASSWARE INDUSTRY.

BY F. W. BRANSON.

In a previous communication* I gave in detail some analytical data as to the composition of practically all the types of important chemical glassware imported prior to the declaration of war and gave preference to a zinc-aluminium borosilicate glass, taking as a starting point for further investigations a Jena glass beaker obtained direct shortly before the declaration of war, the composition of which was:—SiO₂ 64.66%, Al₂O₃ 6.74%, ZnO 10.12%, CaO 0.08%, MgO 0.13%, K₂O nil, Na₂O 7.21%, B₂O₃ 11.14%, Fe₂O₃ 0.10%.

Numerous analyses and experimental meltings made with proportions of zinc oxide varying from 4% to 10% indicate that a percentage of alumina equal to about 6.5% of Al₂O₃, and a percentage of ZnO of 7.5%—8.5% and of boric oxide (B₂O₃) about 7% will give a good glass if perfectly

* This J., 1915, 471.

annealed, equal to all reasonable requirements for scientific work, provided the silica and alkali (or alkalis) are present in the best proportions. With regard to the presence of calcium oxide in glass similar to the above it has been suggested that if zinc oxide is reduced in a formula for resistance glass, lime is the best substitute.* A good deal of experience has been obtained in manufacturing on a large scale in which the percentage of alumina used was similar to that in the general formula given for a good resistance glass, and it is clear that a proportion of about 6% of alumina gives increased strength to glass and, as pointed out by Wood, the presence of alumina in a batch mixture diminishes considerably the action of melted glass on the pots.†

The earliest satisfactory output on a manufacturing scale was obtained, so far as my knowledge goes, by the York Glass Co., Ltd., who repeated my laboratory experiments in their works, using cryolite as a part source of alumina. A zinc-aluminium boro-silicate glass obtained by the use of a good formula is not an expensive glass to make and does not devitrify. It has good working properties and is therefore a favourite one with workmen owing to its good plasticity over a wide range of temperature. It makes excellent glass tubing (especially thin glass tubing) for the manufacture of glass apparatus and ampoules. In addition to the above, a considerable quantity of aluminium boro-silicate and other types of scientific glassware of excellent quality is being made by several firms. Analyses published in 1917 of all the British glasses then made, by W. E. S. Turner and his colleagues (J. Soc. Glass Tech., 1917, 1, 196) show that all are better than any pre-war imported glassware and that three of the series are superior to the other British glasses; two of these appear to have been made from the same or a very similar formula to that previously referred to, whilst the third has a lower zinc content and lime is added in place of a proportion of the zinc.

A great aid to the industry would be the standardisation of hollow scientific glassware such as beakers and flasks as to shape, contents, weight, etc. There is at present no lead as to what the total content of say a nominal litre (or other size) beaker or flask should be, nor is there any official recommendation as to the range of sizes. Travers has suggested definite thicknesses and weights for certain apparatus,‡ and I have advocated that steps should be taken to give an official lead to the trade. I have in conjunction with Messrs. Douglas H. Baird and Frank Wood presented a report accompanied by a set of scale drawings of a complete series of beakers and flasks, which by permission of the Department of Scientific and Industrial Research (Sub-Committee on Glassware Testing and Standardising Glass and Optical Instruments) is available for publication, with a view to adoption by all British manufacturers. To give a single example as to unnecessary sizes:—40 plain beakers were listed by the principal British and Continental manufacturers in the years 1914 and 1915. This number has been reduced in the Report referred to, to 21, namely:—30, 50, 75, 100, 125, 150, 175, 200, 250, 300, 400, 500, 600, 800, 1000, 1250, 1500, 2000, 3000, 4000, 5000 c.c. In addition, spouted beakers were reduced from 33 sizes to 22, flasks (round or flat bottom) from 26 to 24, beaker flasks from 11 to 9, and distilling flasks from 19 to 13. If we are to resist successfully foreign competition after the war there should be no redundant sizes; the abolition of such would mean economy to manufacturers, distributors, and users; lower freight

charges would also be attained, and indeed economy secured in every direction.

I would suggest that a committee be formed to include one nominee each from the Society of Chemical Industry, The British Chemical Ware Manufacturers' Association, Ltd., The British Laboratory Ware Association, Ltd., and the Society of Glass Technology, and one other to represent the actual workers in the scientific glassware industry, to draw up a report showing what sizes are unnecessary or to make such alterations as may be necessary, with power to co-opt other members (not exceeding two) if thought necessary. At a later stage graduated and other instruments could with advantage be taken in hand by this committee. One problem, namely, the question of a standard taper for stoppers for burettes, gas analysis apparatus, etc., has been carefully considered by A. M. Rowland, who suggests an angle of about 9° (see J. Soc. Glass Tech., 1917, 1, 103).

With regard to graduated scientific glassware it is interesting to note that at the National Physical Laboratory steps have been taken to extend greatly the existing facilities for testing, stamping, and granting of certificates for approved instruments. If a nominal charge for testing British graduated glassware could be made, the manufacture and use of verified instruments would be greatly extended. The Ministry of Munitions has ordered that all clinical thermometers sold after Nov. 21, 1918, must bear the approved test mark of the Laboratory. Unless full use is made of the resources of the National Physical Laboratory it is feared that inaccurate apparatus will be manufactured (or perhaps imported) and supplied, the result being dissatisfaction.

In addition to the Class A tests (such as are used for clinical thermometers), a Class B grade of commercial accuracy (say with an increased tolerance of 50% compared with Class A) has been adopted, and if in the future it be found possible to have sub-stations in the provinces for testing the Class B instruments, a very much larger number of pieces of apparatus can be dealt with at a minimum of cost. That a necessity urgently exists for such tests is obvious from the inaccurate graduated instruments exhibited.

An interesting section of my research was that which related to annealing, as in the early stages of the manufacture of British chemical glassware considerable difficulties were encountered. I cannot emphasise too strongly the importance of adequate annealing as I have repeatedly found that glassware made from the same formula by different firms varied greatly as regards internal stress. A careful determination was therefore made as to the exact temperature for annealing without deformation a glass which approximated in composition to the general formula already given, and this was found to be 580° C. by means of an accurate pyrometer and Hilger's strain viewer.

Twyman* has determined the variation of the viscosity of glass with temperature in the case of a variety of glasses and gives a formula which applies throughout the ranges of temperature of interest for purposes of annealing. Combining this formula with the expressions given by Maxwell for the disappearance of stress in a viscous body, it is possible (by measuring the viscosity of the glass at any convenient temperature by means of the apparatus) to find the annealing temperature of any sample of glass. Repeated trials show that the results so obtained are entirely satisfactory.† Having ascertained the correct

† See also English and Turner, J. Soc. Glass Tech., 1918, 2, 90.

annealing point, an experiment was made to find whether any improvement resulted by re-annealing, and I wish to express my indebtedness to Messrs. John Moncrieff, Ltd., of Perth, for making a batch of glass on a manufacturing scale and annealing beakers made from it at a temperature of 550° C. and after cooling, re-annealing them at the same temperature. These beakers were carefully tested for stress by the method already referred to and found to be "Well annealed" and "Perfectly annealed" respectively. Mr. A. Chaston Chapman reported that the re-annealed beaker was more resistant to chemical reagents than the "single" annealed beaker. Further research is desirable to decide if re-annealing is of any practical value.

In both peace and war the scientific glassware industry is of such great importance, as so many other industries are directly dependent on it and as it is certain that but for the stocks of merchants at the time of the declaration of war a very serious crisis would have occurred, that it should, I think, be regarded as a "Key Industry" and receive state assistance to the fullest possible extent; liberal special grants being allocated to the National Physical Laboratory, Departments of Universities such as the Glass Technology Department of the Sheffield University, Research Departments of organised trades such as the scientific glassware industry, and technical institutions in which glass technology is a subject.

I wish to express my indebtedness to Mr. F. H. Branson for his assistance with numerous analytical and experimental operations.

DISCUSSION.

The CHAIRMAN said that in the main he agreed with Mr. Branson as regards standardisation, but there was always the possibility that if once they began to depend on other people for standardising their instruments the habit of standardising—and it ought to be a habit—might easily be lost. Personally he thought it was important that every worker should standardise his own instruments. With regard to clinical thermometers, it must not be overlooked that they were apt to change when in use. So long as it did not interfere with a man taking the responsibility of his own instruments he did not find serious fault with the suggestion, but personally he was rather against subsidisation by the Government.

Dr. W. B. DAVIDSON agreed with the Chairman that every laboratory should standardise its own instruments, whether of glass or other material, and no graduated instrument should be accepted without testing. It was their business to eliminate all sources of error as far as they could, and it was quite possible with care to get down to as low an error as 1 in 5000. He was quite in agreement on the question of stoppers—as to the taper or angle. That was one of the weaknesses of the glass industry at present—that it could not turn out stoppers in sufficient numbers which did not give a great deal of trouble. A good deal of trouble also arose from bad annealing, especially in regard to large glass tubes, funnels, etc. On the other hand, British glass manufacturers deserved credit for the excellent quality of the material they had turned out during the war.

Mr. F. W. RICHARDSON suggested that makers of pipettes should be urged to put only a small graduation mark on these instruments, which would not look so unsightly as the heavy marks at present used when supplemented by the analyst's own graduation marks.

Dr. W. E. S. TURNER said that he supposed no one would be averse to purchasing an accurate

instrument if it could always be relied on. It was because of their experience that manufacturers' marks were sometimes inaccurate that they had found it necessary to calibrate measuring vessels for themselves. Mr. English, whose method of rapidly calibrating pipettes was mentioned by Mr. Branson, was engaged in completing a similar method applicable to burettes. The method for pipettes was one intended to combine speed and accuracy.

Prof. J. W. COMB said that if the apparatus that Mr. English had devised would enable scientific workers to be supplied with instruments that did not need re-calibration, it would at any rate save time; but even so he considered that chemists should carefully test the calibrations supplied before finally accepting them as correct. Although British glass-makers had achieved considerable success during the war and a large amount of research had been carried out in this country, the difficulties of glass manufacture had not yet been completely overcome, and a great deal of experimental work would be required both in the laboratory and in the works before the manufacture could be said to have been put on the desired footing. With reference to some of the tests that had been carried out in relation to resistance of glass to reagents, he recalled an experience of his own some time ago in determining soluble silicates after heating certain mixtures, when he had come to the conclusion that neither the acid nor the alkali test was trustworthy alone and that it was necessary in order to obtain trustworthy results to follow the one by the other.

Dr. W. E. S. TURNER, referring to the composition of glass, said it appeared that the zinc-aluminium boro-silicate glass was one of the best on the market and emphasised the value of zinc as a constituent. This did not mean, however, that a glass equally good but not containing zinc could not be obtained. Under some conditions a much simpler glass could be employed, and he had in mind in particular a specimen of a simple kind imported from America which was as good in point of resistance to water and acid as anything we had. With regard to the difference in chemical resistance between partly annealed and well annealed glass, he would certainly have expected such difference to exist, if only by analogy with metals in the hardened and annealed states (although he was aware the analogy was imperfect). But all the results obtained in his own laboratory and all the results from other sources which had come to his notice failed to reveal any difference in resistant power due to re-annealing. He was afraid he could not attach much weight to the figures quoted by Mr. Branson in this connexion, and Mr. Branson had rightly advised caution. The Jena factory, where re-annealing was carried out with flue-gases containing sulphur dioxide, held that there was a considerable improvement in resistance to water. Tests with acid and alkali, however, carried out at the National Physical Laboratory, failed to bring to light any difference between the ordinary and the re-annealed glass. The question of standardisation of sizes of glass articles had been raised by Dr. Travers at the Annual Meeting of the Society at Bristol last July (this J., 1918, 238T); but even before that the matter had received considerable attention by a sub-committee of the Department of Scientific and Industrial Research. Perhaps something would now be done to ascertain what sizes users generally thought most convenient.

Mr. BRANSON, in reply, expressed his agreement with Dr. Davidson with regard to the personal checking of important graduated instruments. With reference to English's method, the inventor

had informed him that with careful practice the working error was very small. He thought that no difficulty would occur in adopting Mr. Richardson's suggestion. With Prof. Cobb's remarks he was wholly in accord, as although a large amount of work had been done under difficult conditions, a wide field yet remained unbroken. Dr. Turner's remark on the new glass was another indication as to the value of the work of the department which he so well conducted.

Communication.

THE AGEING OF VULCANISED PLANTATION RUBBER.

PART II.

BY HENRY P. STEVENS.

In a previous paper (this J., 1918, 305 T) I dealt with ageing experiments on ordinary sheet and so-called "slab" rubber. The present communication contains the results of an exactly similar series of experiments on smoked sheet, smoked "slab," ordinary pale crêpe, and smoked crêpe. Reference should be made to the first paper for the scheme of the experiments.

The figures for the coefficients of vulcanisation determined at the commencement and conclusion of the ageing experiments were as follows:—

Hours vulcanised	(1) <i>Smoked Sheet.</i>		(2) <i>Smoked Slab.</i>		(3) <i>Pale Crêpe.</i>		(4) <i>Smoked Crêpe.</i>	
	Beginning of ageing period	End of ageing period	Beginning of ageing period	End of ageing period	Beginning of ageing period	End of ageing period	Beginning of ageing period	End of ageing period
2	2.66	2.57	2.82	2.92	2.01	2.26	2.11	2.25
3	3.06	3.04	3.37	3.53	2.86	2.66	2.75	2.80
4	3.72	—	4.14	4.42	3.62	3.58	3.45	—
5	4.33	4.38	4.81	5.63	4.27	4.28	4.17	4.21
6	4.87	5.51	5.54	6.16	4.86	—	4.92	5.11
7	5.68	6.31	6.27	6.80	5.94	—	5.57	5.88

These figures confirm the previous conclusion, namely, that the increase with age in the coefficient is more noticeable in the over-vulcanised samples. Thus, an analysis of the above figures and those given in the previous paper gives the following results:—

Average coefficients between	Average increase in coefficient during ageing period.
2 and 3 = 2.52	0.02
3 and 4 = 3.43	0.10
4 and 5 = 4.55	0.25
5 and 6 = 5.69	0.51

The curves for breaking strain and elongation are similar to those published in the previous paper. The maximum breaking strains are those obtained from tests made shortly after vulcanisation and correspond to coefficients of 4 to 5. Tabulating the results as above, we have

Average coefficients between	Maximum breaking strain.
2 and 3 = 2.52	1560
3 and 4 = 3.43	1930
4 and 5 = 4.55	2090
5 and 6 = 5.69	1790
over 6 = 6.56	1580

These figures show clearly that the maximum breaking strain is not attained without considerably overcuring the rubber. The diagrams show that all types of rubber, when cured to give a coefficient of

4–5, attain the maximum breaking strain within 10 or 15 weeks of vulcanisation, after which they rapidly lose strength. In a year or so they become hardened and perished. On the other hand, if the vulcanisation be carried only so far as corresponds to a coefficient of 2–3, there is obtained with all types of rubber a product which, although only of medium strength when freshly cured, improves on an average for about a year and then only very slowly loses strength, so that at the end of two years the rubber is still stronger than when first vulcanised.

In the first paper figures were given showing the correlation of the coefficient and the period during which increase in breaking strain takes place. If these figures are analysed and the averages calculated as above the following are obtained:—

Average coefficients between	Average period (weeks) during which increase in breaking strain takes place.
2 and 3 = 2.52	54
3 and 4 = 3.43	33
4 and 5 = 4.55	10
5 and 6 = 5.69	3
over 6 = 6.56	nil

If the various diagrams be compared, it will be noted that the position of the curves is dependent on the coefficient and not necessarily on the time of cure, showing that the coefficient is the essential index of the degree of vulcanisation.

The curves for the same coefficient for different types of rubber do not necessarily coincide, for it has been shown in a previous paper (this J., 1918, 280 T) that the load required to produce a given elongation in sheet rubber is greater than in crêpe rubber when both types are cured to give the same coefficient. The curves for elongation all slope downwards, showing a gradual reduction in the final length with the period of ageing. With low coefficients the reduction is very gradual; with coefficients over 5 the vulcanised specimens are perished before the full period of ageing is completed. The average figures are as follows:—

Average coefficients between	Percentage decrease in final length.
2 and 3 = 2.52	7.7
3 and 4 = 3.43	13.9
4 and 5 = 4.55	39.9
over 5 = 6.02	nearly 100

The elongations corresponding to low coefficients for ordinary sheet rubber given in the first paper show an upward tendency during the first few weeks. This was not noticed with the curves for the unrolled sheet, nor is it found in the elongation curves here reproduced. In fact the reverse tendency is noticeable in the curves for smoked slab and pale crêpe, the curves corresponding to the low coefficients falling a trifle more rapidly during the first few weeks than at a later stage. It is probable that these fluctuations are due to variations in temperature during the period of ageing, and that at a constant temperature the curves for low coefficients would slope uniformly from the commencement of the ageing period. The curves with coefficients under 3 are practically straight lines within the period of ageing. With higher coefficients the curve is steeper and the reduction in final length is accelerated in relation to the ageing period.

Conclusions.

These experiments illustrate the general instability of vulcanised rubber in contrast to the raw material. I have found that plantation rubber may be stored for ten years without showing any change in feel or appearance and, when vulcanised, gives results comparable with those yielded by the freshly

harvested raw material. On the other hand, vulcanised rubber, however carefully vulcanised, commences to change in physical properties from the moment the vulcanisation process is completed. When the original coefficient exceeds 3, appreciable deterioration takes place in 2 years. This may result in a loss of 50% of the tensile strength when the coefficient reaches 4, and complete "perishing" with a coefficient of 5 or more. Under the condi-

tions of the experiments it is apparent that a reasonably permanent product of primary vulcanisation can only be obtained when the coefficient does not exceed 3, and I regard this figure as a suitable standard for vulcanisation when comparing the physical properties of different specimens of vulcanised rubber.

I am indebted to the Rubber Growers' Association for permission to publish these results.

ABSTRACTS

I.—GENERAL; PLANT; MACHINERY.

PATENTS.

Ammonia compressors [for refrigerating machines]. Apeldoornse Machinefabriek en Metaalgieterij voorheen L. Landaal, Apeldoorn, Holland. Eng. Pat. 111,101, Oct. 11, 1917. (Appl. No. 14,735 of 1917.) Under Int. Conv., Nov. 8, 1916.

Is a water-cooled ammonia compressor the outer frame surrounds part of the horizontal cylinder and supports it on two bearing surfaces, the frame between these points forming the outer wall of the water jacket at the middle portion of the cylinder. The cylinder is also supported in a registering recess near the cylinder cover, which is provided with a studding-box. The ammonia is supplied to the cylinder through a closed conduit passing longitudinally through the water jacket space on the upper side, and delivered through a similar conduit on the lower side. These conduits are controlled by valves accessible through openings in the outer frame. The inlet and outlet for the water jacket are arranged at such a height that the level of water in the jacket does not reach the suction conduit and surrounding parts which are cooled by the cold ammonia.—W. F. F.

Graphite crucibles. R. W. James, London. From E. Rietz, Sao Paulo, Brazil. Eng. Pat. 111,152, Nov. 14, 1916. (Appl. No. 16,295 of 1916.)

Is making graphite crucibles, 5 to 40% of compounds of the rare earth metals (e.g., thorium, zirconium) is mixed with the graphite. Zirconium compounds, especially the oxide, are found to be particularly suitable. A typical mixture consists of 10% of zircon earth, 70% of graphite, and 20% of clay, kiln brick, and sand. The crucible after moulding is baked at 1000° C.—J. H. P.

Fire extinguishers; Chemical recharge for—. G. J. Money, London. Eng. Pat. 111,403, Feb. 28, 1917. (Appl. No. 2969 of 1917.)

A CHEMICAL fire extinguisher comprises a hermetically sealed glass bottle containing carbon tetrachloride and dilute sulphuric acid of the same specific gravity. A more intimate mixture is thus obtained when the bottle is broken and the contents added to alkali in the usual manner.

—W. F. F.

Furnaces for generating heat. W. Thomas and A. E. Mainwaring, Nanaimo, B.C., Canada. Eng. Pat. 111,413, Mar. 29, 1917. (Appl. No. 4549 of 1917.)

Is a furnace suitable for burning low-grade or other fuel, such as mine waste, lignite, and the like, for heating steam boilers, bakery ovens, brick and pottery kilns or roasting furnaces, lime and cement kilns, or retorts, etc., the fuel is fed horizontally into one end of the upper part of the furnace chamber, where it is gasified and coked by poorer hot gases from the heated fuel which has settled into the lower wider part of the chamber. An exhaustor mounted above the

furnace draws combustible gas from the top of the furnace and delivers it through a special arrangement of flues in the furnace walls to an adjacent secondary combustion chamber, with which the lower part of the main furnace chamber also communicates directly. A blower, also mounted above the furnace, delivers air for combustion through heating tubes in the uptake from the secondary combustion chamber, and thence through another series of flues in the furnace walls to the secondary combustion chamber, where it is discharged through ports adjacent to the gas ports. A steam generator or the like is arranged above the secondary combustion chamber.

—W. F. F.

Grinding mills; Separator for—. E. J. Steckle, Dixon, Ill. U.S. Pat. 1,244,788, Oct. 30, 1917. Date of appl., Feb. 26, 1917.

A CYLINDRICAL separating chamber has a vertical inlet pipe extending into the lower end, through which a blast of air laden with the ground material is introduced. An outlet pipe is fixed in line with the inlet pipe in the upper end of the chamber, and a baffle which can be varied from the shape of a hood to an inverted hood is fixed between the pipes.—J. H. P.

Grinding-mill. J. B. Shackey, San Francisco, Cal. U.S. Pat. 1,245,625, Nov. 6, 1917. Date of appl., Mar. 23, 1914.

A GRINDING-MILL comprises a pan having an annular horizontal grinding track and a central vertical rotating shaft. The shaft carries a driving spider having vertical guideways sliding on the shaft, and separate members, carrying antifriction rollers at top and bottom, slide vertically in the guideways. Each member carries a short radial shaft on which a roller is mounted which bears on the grinding track, and the driving spider is supported from these shafts by springs.—W. F. F.

Liquids used for separating solids of different specific gravity: Process of recovering—. A. Nagelvoort, New York, Assignor to Virginia Haloid Co., Wilmington, Del. U.S. Pat. 1,244,884, Oct. 30, 1917. Date of appl., June 16, 1916.

THE process relates to the recovery of a liquid which has been used to separate solids of different specific gravities and which has a specific gravity intermediate between those of the solids. The separating liquid is removed by washing with an inert solvent of lower boiling point, at a temperature above the melting point of the separating liquid but below the boiling point of the solvent, and the solvent is evaporated.—J. H. P.

Separating solids of different specific gravities: Process of—. A. Nagelvoort, New York. Assignor to Virginia Haloid Co., Wilmington, Del. U.S. Pat. 1,244,885, Oct. 28, 1917. Date of appl., Sep. 1, 1916.

THE solids are separated in a solution of two

liquids of different specific gravities, each greater than that of water, the lighter liquid (e.g., carbon bisulphide) having a substantially lower boiling point than the heavier (e.g., a "relatively heavy salt"). The heavier constituent of the separant is removed from the separated solids by washing with the lighter liquid, and sufficient of the latter is distilled from the solution to leave a residue in the proportions of the original separating mixture.—J. H. P.

Pulverising molten materials: Method and apparatus for —. W. Freeman, Tacoma, Wash. U.S. Pat. 1,245,328, Nov. 6, 1917. Date of appl., Sep. 6, 1916.

A hollow tubular jet of gas is projected horizontally from a nozzle, a gap is formed in the upper side of the jet, and the molten material is fed in a freely falling stream into the gap, so that it is pulverised and conveyed by the jet.—W. F. F.

Mixer: Continuous —. T. B. Headley, Assignor to G. L. Headley, and Headley Good Roads Co., Philadelphia, Pa. U.S. Pat. 1,246,003, Nov. 6, 1917. Date of appl., Mar. 29, 1917.

FLUIDS to be mixed are fed into a long horizontal cylinder by a mixing nozzle or by supply pipes spaced along the cylinder. A discharge opening is provided at or near one end, and the fluids are fed towards the opening against the opposition of a mechanical conveyor and one or more throttling plates.—W. F. F.

Furnaces. London Electric Supply Corporation, Ltd., and A. G. Fox, London, Eng. Pat. 111,320, Nov. 17, 1916. (Appl. No. 16,515 of 1916.)

Deflocculating solid materials: Method of —. E. G. Acheson, New York, Eng. Pat. 111,434, May 19, 1917. (Appl. No. 7247 of 1917.) Under Int. Conv., Jan. 17, 1917.

See U.S. Pat. 1,223,350 of 1917; this J., 1917, 586.

Refrigerating apparatus. J. C. Bertsch, New York, U.S. Pat. 1,245,179, Nov. 6, 1917. Date of appl., June 21, 1915.

See Eng. Pat. 108,759 of 1916; this J., 1917, 1086.

IIA.—FUEL; GAS; MINERAL OILS AND WAXES.

Carbonisation of coal. F. D. Marshall, Gas. J. 1917, 140, 465.

WHILST the chief aim of high-temperature carbonisation is the production of a maximum yield of gas, the aim of low-temperature carbonisation is the production of an easily ignitable coke burning brightly with practically no smoke. In addition, from coals, cannel, shales, and lignite, quantities of oil may be obtained varying from 16 gallons in the case of colliery refuse to 87 gallons in the case of cannel. From these, petrols, burning oils, Diesel oils, lubricating oils, paraffin wax, tar acids, and a valuable bituminous pitch, can be obtained. The gas is "stripped" to recover additional petrol, and this, together with the petrol obtained by fractionating the crude oils, gives a total of 4 to 8 gallons of petrol per ton of coal. The gas after "stripping" is used as retort fuel. The above results are obtained by carbonising in iron retorts of special construction at a temperature from 900° to 1200° F. (480° to 640° C.) and under a vacuum of 10 to 20 ins. of mercury. The author and his colleagues claim to have established the fact that 5 in. is the maximum thickness of charge for low-temperature processes, and have on hand several large installations, in all of which retorts taking one ton per charge of four hours will be installed.—J. E. C.

Light oils [benzol]: Recovery of — from coke-oven gas. W. H. Wright, Amer. Gas Inst. Gas J., 1917, 140, 462.

THERE are at present 43 plants in the United States recovering light oils, with an approximate output of 110 million gallons as against 10 million gallons in 1913. The first attempt to recover benzol was made by Vogel in 1859, fatty oils being used for absorption with the idea of increasing their value for illuminating purposes. A patent was taken out by Carvès in 1884 for the recovery of benzol in connection with his coke ovens, heavy tar oil being used in an intermittent process. The first continuous plant of any size was built by Brunck in 1894. The general type of scrubber used in the United States appears to be of the tower form, from 6 to 24 ft. in diameter, and 40 to 90 ft. high, uniformly filled with wood grids. Experience has shown that it is desirable to have not less than three towers in a series, the wash-oil being circulated in counter-current to the gas, and in sufficient quantity to bring about a saturation of the benzolised oil to about 2 or 3%. Tar oil is used as an absorbent in Europe, and high-boiling petroleum oils in the United States. Plants at which still temperatures of about 135° C. are obtained show better wash-oil results than plants working at lower temperatures. The time of contact of the gas and oil in the majority of plants is from 70 to 100 seconds. The absorbing power of the oil commences to drop off very rapidly at about 25° C., so that it is important to keep the temperatures of gas and wash oil below this figure. In European plants the benzolised oil passes first through an oil-to-oil heat exchanger, then through a vapour-to-oil exchanger, whilst in America this sequence is reversed. Experience has fully demonstrated the desirability of the use of superheated steam. The author suggests the use of the single-pipe refrigeration ammonia cooler for cooling the wash oil, also that the cooling be brought about with the wash oil inside the tubes, and water outside, down to about 40° F. (4.5° C.), and the remainder of the cooling with oil outside and water inside. The reduction in heat value and illuminating power is given as 10 B.Th.U. and 2.3 candles respectively per 0.1 gall. of light oil removed per 1000 cub. ft.—J. E. C.

Benzol-recovery plant operation: Laboratory methods for —. F. W. Sperr, jun. Met. and Chem. Eng., 1917, 17, 548—555.

THE author describes the benzol recovery system of the H. Koppers Co., and enumerates the routine tests required in the operation of such a plant. To determine the light oil in the gas, a sample is drawn off from the main through a series of eleven wash-bottles and then through a meter. The connecting tube from the main to the first wash-bottle is heated by a steam-jacket to prevent deposition of naphthalene. The first wash-bottle contains strong caustic soda solution; the remainder contain wash oil and are kept below 20° C. throughout the test. When a suitable quantity of the gas has been passed through, the oil is emptied into a copper still and steam-distilled until about 500 c.c. of water has passed over, the oil in the still being maintained at 170°—180° C. The oil in the distillate is then separated from water, dried, and redistilled, the volume distilling below 200° C. being noted. To estimate the benzene, toluene, and solvent naphtha content, the oil is purified by successive treatment with sulphuric acid, caustic soda solution, and warm water, dried over solid calcium chloride, and fractionally distilled. A weighed sample is transferred to a distilling flask fitted with a fractionating column and distilled at a rate not faster than one drop per sec. to 130° C. (fraction "A"); the collecting flask is then changed and the distillation

resumed to 200° C. ("B"). "A" is then redistilled at the rate of one drop per 2 seers. "C" being the fraction collected to 95° C., and "D" the fraction to 120° C. "C" is again redistilled very slowly to 95° C. ("E"). Each sample is collected in a glass-stoppered Erlenmeyer flask and weighed. "E" = wt. of benzene content; "D" + ("C" - "E") = wt. of toluene content; "B" + ("A" - "C" - "D") = wt. of solvent naphtha content. Percentages by volume may be calculated by taking the sp. gr. at 15° C. of "E" for benzene, "D" for toluene, and "B" for solvent naphtha. The percentage of non-aromatic hydrocarbons in each fraction can also be calculated (Rittman and others; this J., 1915, 1080). This method of analysis of light oils gives good results (to within 1%) if the benzene content is at least 50%, and the toluene content not over 30%; if this is not so, pure benzene may be added to bring the composition of the sample within the limits. Other methods for the analysis of light oils are described briefly. The percentage of wash oil in light oil is determined by distilling 1000 c.c. at first dry to 120° C., and then with the introduction of steam, keeping the oil between 120° and 130° C. The residual oil in the still is cooled and filtered free from naphthalene. A blank experiment is run by distilling similarly 1000 c.c. of wash oil.—L. A. C.

Solvent gasoline. C. O. North. J. Ind. Eng. Chem., 1917, 9, 1038—1043.

LABORATORY experiments are recorded on the cracking of heavy mineral naphtha, crude oil, and heavy kerosene for a solvent gasoline suitable for rubber manufacture. The oil was distilled under pressure from an iron still of about 1½ gallons capacity and the vapour passed through a cracker consisting of a gas-heated iron tube connected with a reflux condenser fitted with a steam jacket. The heavier vapours were then returned for further cracking, while the lighter passed forward to be condensed and collected. Gases formed were collected in a small holder. The deposition of carbon in the cracker was not excessive at the temperature of working (a dull red heat). Heavy kerosene gave the most satisfactory results. The yield of solvent gasoline (30°—130° C.) was up to 16.4% and of motor gasoline (30°—150° C.) up to 23%.—H. J. H.

Utilisation of grape marc as fuel. Matignon and Marchal. See XVIII.

PATENTS.

Mixing powdered fuel and air: Apparatus for —. H. A. Gill. London. From Powdered Coal Engineering and Equipment Co., Chicago, Ill., U.S.A. Eng. Pat. 111,412, Mar. 26, 1917. (Appl. No. 4322 of 1917.)

POWDERED fuel is supplied by the conduit, 19, to the perforated mixing chamber, 16, and air is supplied by the conduit, 13, to the annular

chamber, 10. The perforations in the chamber, 16, are punched inwards so as to form louvers and produce a number of air jets in all directions in the mixing chamber, and the openings, 18, at the rear end are made larger. When an additional supply of fuel is required, the feed may be aug-

mented by admitting air to the injector nozzle, 21, through the valve, 22. When an additional supply of air is required to produce a longer flame, it may be supplied by opening the annular valve, 24, by means of the screwed rod, 25, and handle, 27.—W. F. F.

Coke-oven walls: Method of repairing —. A. H. Chalmers, Fairfield, Ala. U.S. Pat. 1,244,467, Oct. 30, 1917. Date of appl., May 1, 1916.

IN a coke oven having vertical openings through the roof leading to combustion chambers in the walls, a beam is supported upon the two walls adjacent to the one to be repaired. A supporting member, suspended from this beam, passes through one of the aforesaid openings and by means of an attached plate supports the roof during repairs to the wall.—J. E. C.

Burners for heavy oils for use in oil furnaces. J. B. Steurs, Seraing-lez-Liège, Belgium. Eng. Pat. 111,249, June 5, 1917. (Appl. No. 8051 of 1917.)

PRIMARY low-pressure air is fed through an adjustable nozzle which passes through the oil supply chamber and regulates the flow of oil. The air and atomised oil pass into a mixing chamber and then through a nozzle into the furnace. Secondary high-pressure air is fed into a chamber surrounding the mixing chamber, and then passes through an annular opening around the nozzle, thus drawing the mixture of low-pressure air and oil into the burner.—L. A. C.

Oils: Process of transforming — into lighter oils. I. H. Wheat-roft, Oklahoma, U.S.A. Eng. Pat. 111,317, Nov. 6, 1916. (Appl. No. 15,868 of 1916.)

CRUDE petroleum or oil distillate is pumped at high speed through a heating coil of small diameter and great length in a furnace, where it is heated to 400°—150° F. (205°—232° C.), and thence at 100 lb. per sq. in. pressure through a jacketed tube heated to 800°—900° F. (427°—482° C.) by superheated steam from a coil in the furnace. At this point about 10% of superheated steam is injected into the oil. The oil then passes through a drum in the upper part of the furnace, heated to a temperature above 1000° F. (540° C.), and provided with a spiral to give the oil vapour a whirling movement. The heavier vapour is thus forced outwards and exposed to a higher temperature than the lighter vapour at the centre, thus causing a more uniform and complete cracking. The vapour then passes to a drum where carbon settles out, and thence to a cooler where the temperature is reduced to about 300° F. (150° C.). The oil gas and vapour then pass to a separator into which superheated steam is passed to raise the temperature to about 350° F. (177° C.), the resulting vapour is passed to a condenser, and the residue pumped back to the original supply tank for further treatment. The condensed liquid passes through a tank and is forced by a pump through a steam-jacketed heater to a steam still heated to 345° F. (174° C.). The vapour passes to a condenser and thence to a storage tank, and the residue is drawn off to a tank from which it may be passed through the first or second steps again as desired.—W. F. F.

Still or rector [for cracking oils]. F. E. Wellman, Kansas City, Kans., Assignor to The Kansas City Gasoline Co., Kansas City, Mo. U.S. Pat. 1,245,291, Nov. 6, 1917. Date of appl., Feb. 23, 1915.

IN a low-pressure cracking system, the vapour space of a vaporiser, 2, is connected by a pipe, 4, to a superheating coil, 5, from which vapour passes upwards by an inclined pipe, 9, to the uppermost coil, 15, of a fractional condenser. Valves are provided between the units of the condenser and also on branch pipes, 16, 16', 16'', which

p-aminobenzoic ethyl ester, 10 lb. of diethylaminoethanol, and 4—8 oz. of the aluminium compound of diethylaminoethanol are heated to 150°—180° C., all the ethyl alcohol formed being allowed to distil off; the excess of diethylaminoethanol is removed by distillation at 27—28 ins. vacuum until the temperature of the liquor has risen to 170° C., when the residue is poured into cold water and neutralised with hydrochloric acid; any unconverted aminobenzoic ethyl ester remains undissolved and is removed by filtration. The diethylaminoethyl ester of *p*-aminobenzoic acid may be precipitated by caustic soda, and the hydrochloride forms a pure white salt. Instead of adding the aluminium compound, it may be formed in the mixture, *e.g.*, by adding 2% of aluminium amalgam.—F. W. A.

IV.—COLOURING MATTERS AND DYES.

PATENTS.

Intermediate products [methylformanilide derivatives] suitable for the manufacture of colouring matters; Manufacture of —. H. Levinstein, Manchester, and G. T. Morgan, London. Eng. Pat. 111,321, Nov. 17, 1916. (Appl. No. 16,520 of 1916.)

p-NITROMETHYLFORMANILIDE (m. pt. 119°—120° C.), its substitution products (other than nitro derivatives), such as halogen or alkyloxy derivatives, and homologues, are produced by nitration at —5° to 20° C. of methylformanilide or its corresponding derivative having a free *para*-position to the amino-group. *p*-Aminomethylformanilide (m. pt. 115°—116° C.),

its substitution products and homologues are obtained by reduction of the corresponding nitro-derivatives by means of reducing agents which do not eliminate the formyl group, *e.g.*, iron borings and dilute formic or acetic acid at 85°—100° C. These products may be used with advantage in the manufacture of dyestuffs, as the formyl group may easily be removed.

—F. W. A.

Dye [compositions]. S. M. Tootal, J. Kershaw, J. Mather, and V. A. Tootal, Blackpool. Eng. Pat. 111,365, Dec. 15, 1916. (Appl. No. 18,025 of 1916.)

A COMPOSITION of a combined dye tint and finish, more particularly suitable for domestic purposes, consists of a mixture of dye with glue or gelatin in the form of a dry circular wafer, zinc oxide, ammonia, or sodium carbonate being added to prevent stickiness.—F. W. A.

[Triphenylmethane] dye; Violet cotton —. M. Weiler, Elberfeld, Germany, Assignor to Synthetic Patents Co., New York. U.S. Pat. 1,244,149, Oct. 23, 1917. Date of appl., Sep. 22, 1915.

DYESTUFFS are claimed, produced by sulphonation of a triphenylmethane compound and of the general formula: $\text{RR}_1\text{C}(\text{R}_2)\text{NH}(\text{R}_3)$, in which R and R₁ are aryl radicals of an aromatic hydroxycarboxylic acid, *e.g.*, hydroxycarboxytoluene, R₂ is a divalent aryl radical of the benzene series, and R₃ is a sulphonated aryl radical. The products give violet shades when printed on cotton in conjunction with a chrome mordant.—F. W. A.

[Sulphur] dyestuffs; Process for the production of —. Z. Suzuki, Los Angeles, Cal. U.S. Pat. (A) 1,244,795 and (B) 1,244,798, Oct. 30, 1917. Date of appl., Oct. 30, 1916.

SULPHUR-CONTAINING dyes are obtained by heating (A) rice hulls or (B) tobacco stems with water and caustic alkali, adding sulphur and sodium sulphide, and continuing the heating until hydrogen sulphide has been evolved and until a dry mass is obtained.—F. W. A.

V.—FIBRES; TEXTILES; CELLULOSE; PAPER.

Sulphite pulps; Method of staining to distinguish between bleached and unbleached —. C. G. Bright, Tech. Assoc. Pulp and Paper Ind., May, 1917. J. Ind. Eng. Chem., 1917, 9, 1044—1045.

THE fibres are first stained with Cross and Bevan's ferric ferriyanide reagent which colours unbleached sulphite green on account of contained lignin, leaving the bleached pulp colourless. The contrast is further increased by subsequently staining with a red substantive dyestuff, when the green changes to a very pure blue and the bleached fibres are coloured red. The ferricyanide reagent is produced by mixing equal volumes of *N*/10 ferric chloride and *N*/10 potassium ferriyanide. The slide carrying the fibres is dipped into this mixture for 15 minutes at 35° C. The red stain is prepared by stirring slowly into hot distilled water 0.4 gm. of Benzopurpurin 4 B. extra and 0.1 gm. of Oxamine Brilliant Red B.X. The immersion lasts 5 minutes. Fresh solutions are used in all cases.—H. J. H.

PATENTS.

Cotton waste or other fibrous material; Apparatus for cleansing —. A. Poulson, Widnes, and W. C. A. Mate, Garstang. Eng. Pat. 110,691, Mar. 6, 1917. (Appl. No. 3276 of 1917.)

AN apparatus for cleansing cotton waste or other fibrous material, especially for use in the manufacture of explosives, consists of an outer tank, 1,

forming with a chamber, 2, channels for collecting the separated dirt. The cleansing liquid on heating circulates upward through tubes, 3, fitted at the top with a deflector plate, 4, having a return flange, 4a, and returns to the chamber, 2, by perforations, 6, in a diaphragm on which rests the material to be cleaned, and the projecting tubular nozzles, 8.—F. W. A.

Cellulosic material; Preparation and treatment of — to render it suitable for use as a substitute for cork and the like. G. E. Heyl, London. Eng. Pat. 110,941, Nov. 8, 1916. (Appl. No. 16,011 of 1916.)

FINELY divided material such as spent hops, ground wood, and other cellulose, with or without finely divided cork, is treated with a fireproofing salt, such as borax or a tungstate, and dried; it is then sprayed with a solution of rubber in naphtha or other solvent and moulded into slabs by passing between heated rollers.—J. F. B.

Paper; Calenders or machines for imparting a tin-faceted or like finish to —. Grove Mill Paper Co., Ltd., and W. Porritt, Stockport, Cheshire. Eng. Pat. 111,024, Mar. 8, 1917. (Appl. No. 3411 of 1917.)

THE calender consists of two bowls, separately adjustable, with means for quickly raising and lowering the lower pressure bowl, and two endless linen or fabric bands passing partly over the bowls in the same direction. The endless bands are supported, one by rollers below the stillage and by rollers on vertical supports at some distance behind, and the other by rollers on horizontal supports above. Both the vertical and horizontal supports carry means for adjusting the tension of the bands, and scroll-rollers are situated near the calender bowls for opening out the upper and the lower bands. After the paper has passed through the calender between the two bands, it is conducted over steam-heated drying rollers and reeled up.—J. F. B.

Paper and method of making the same. E. F. Millard, Watertown, Mass. U.S. Pat. 1,244,116, Oct. 23, 1917. Date of appl. June 7, 1916.

PAPER stock consisting substantially of short thin raw wood fibres is prepared mechanically from raw wood, and in a separate operation a pulp of relatively longer fibres is also prepared mechanically from raw wood. The two pulps are mixed in equal proportions to form a pulp mixture containing sufficient long fibres to loosen up the short fibres and facilitate the running of the pulp, combined with sufficient short fibres to impart strength and finish to the paper.—J. F. B.

Paper pulp; Process of manufacturing —. T. Marusawa, Fukuoka, Japan. U.S. Pat. 1,244,525, Oct. 30, 1917. Date of appl. Aug. 2, 1917.

VEGETABLE fibrous material is boiled with ammonium bisulphite, or a mixture of ammonium bisulphite with sulphurous acid or a soluble sulphite, an acidity of 0.1 to 0.8-N being maintained. The boiling may be carried out in two stages.—F. Sp.

Pulp and other material; Presses for expressing liquids and forming articles from —. W. J. Norris, London. Eng. Pat. 111,327, Nov. 18, 1916. (Appl. No. 16,574 of 1916.)

Artificial silk and like threads; Apparatus for treating —. H. de Chardonnef, Paris. U.S. Pat. 1,215,690, Nov. 6, 1917. Date of appl. Mar. 3, 1917.

SEE Eng. Pat. 10,858 of 1915; this J., 1916, 320.

VI.—BLEACHING; DYEING; PRINTING; FINISHING.

PATENTS.

Cloth dyeing, bleaching, and like machines. R. Jackson, Chinley. Eng. Pat. 110,715, May 24, 1917. (Appl. No. 7180 of 1917.)

IN a cloth dyeing, bleaching, or like machine, the

cloth, whilst held taut, is passed at a uniform speed below the surface of the liquor by means of two guiding rollers, and squeezed across its entire width before and after being passed through the liquor by means of squeezing rollers, one above each guiding roller; the motion for winding and unwinding is obtained from the squeezing rollers.—F. W. A.

Dye [compositions]. Eng. Pat. 111,365. See IV.

Soapy liquors from laundries; Method of treating waste —. E. W. Lucas, Ealing, Assignor to H. P. Denison, Syracuse, N.Y. U.S. Pat. 1,215,695, Nov. 6, 1917. Date of appl. Apr. 17, 1914.

SEE Eng. Pat. 10,280 of 1913; this J., 1913, 941.

Fast tints; Process for producing —. G. Engi, Assignor to Society of Chemical Industry in Basle, Switzerland. U.S. Pat. 1,245,694, Nov. 6, 1917. Date of appl. Nov. 4, 1915.

SEE Eng. Pat. 13,204 of 1915; this J., 1916, 419.

VII.—ACIDS; ALKALIS; SALTS; NON-METALLIC ELEMENTS.

Sulphuric acid; Concentration of —. P. Pipereaut and Hellbronner. Monit. Scient., 1917, 61, 265—269.

THE concentration of dilute sulphuric acid, as usually carried out by means of hot flue gases passed in counter-current over the acid in a series of volvic stone vessels, has the disadvantage of causing considerable loss of acid in the vapours. This is due to the comminution of the acid and the formation, under the action of the hot blast, of a considerable amount of anhydride from the concentrated acid, which is only condensed with difficulty in water or weak acid. The authors therefore propose to reverse the usual process and pass the acid in a shallow undisturbed stream, through a series of twelve vessels of special design, in the same direction as the flue gases. Each vessel is in the form of a rectangular box, 1 metre long, 1.5 m. wide, and 0.5 m. high, provided with circular inlet and outlet, the latter at a lower level than the former, and keyed together. Sodium silicate is used to make the joints tight, and the whole is covered with sheet lead 10 mm. thick. The acid to be concentrated is introduced into the first vessel through a pipe in the side. Every alternate vessel is provided with a pipe through which any desired proportion of vapour may be led away for condensation. Gases at 1200° C. can be employed directly on acid of 53° B., and the proportions should be adjusted so that (a) the concentrated acid is not heated above 300° C., at which temperature anhydride formation begins, and (b) the gases leaving the system are still considerably below the point of saturation with water vapour. The advantages claimed for the system are economy of fuel, low acidity of the condensed vapours, reduced atmospheric pollution, and smaller wear and tear of the plant.—F. Sp.

Chlorides; McLean-Van Slyke iodometric method for the titration of small amounts of halides, in its application to —. R. F. McCracken and M. D. Walsh. J. Amer. Chem. Soc., 1917, 39, 2501—2506. (See this J., 1915, 608, 1033.)

VARIATIONS in the amount of citrate used, from 10% below to 21% above that prescribed by McLean and Van Slyke (see this J., 1915, 608; the sodium citrate referred to there is the salt with 5½ mols. of water), do not seriously affect the end-point in the titration with potassium iodide solution provided this is completed without delay. When the titration with potassium iodide is carried out very slowly a blue coloration, which might be mistaken for the end-point, sometimes

develops before the titration is complete. This coloration disappears as the end-point is reached. There is a possibility of slight errors due to adsorption of silver nitrate by the silver iodide formed, if the latter is allowed to agglomerate; this may be avoided by addition of 10 c.c. of 1% starch solution immediately before titration, whereby the silver iodide is retained in solution. The method, applied to amounts of pure sodium chloride up to 100 mgrms., gave a maximum error of 0.24 mgrm.—J. H. L.

Hydrogen peroxide: Action of—on the neutral salts of lead. V. Zotier. Bull. Soc. Chim., 1917, 21, 241—243.

NEUTRAL lead salts exert a more or less marked catalytic action on hydrogen peroxide (100 vols.), the catalysis being intense with soluble organic salts and feeble with insoluble organic salts or mineral salts. With a salt such as lead acetate the ultimate result is the complete decomposition of the hydrogen peroxide, and the lead acetate contains no residual lead peroxide (see also J. Chem. Soc., Jan., 1918).—W. G.

Lead: Some compounds of—. [Detection of hydrogen peroxide and of lead; preparation of red lead.] V. Zotier. Bull. Soc. Chim., 1917, 21, 244—246.

By the addition of hydrogen peroxide to a solution of lead nitrate in 20% sodium hydroxide, a 40% yield of pure lead peroxide is obtained. Hydrogen peroxide at a dilution of 0.006 gm. per litre may be detected by the addition of a trace of an alkaline solution of a lead salt, and, conversely, lead at a dilution of 0.0025 gm. per litre may be detected by neutralising the solution, adding an excess of hydrogen peroxide, and then, drop by drop, a 1% solution of sodium hydroxide. Amorphous red lead is obtained by heating together equal weights of lead nitrate and 50% sodium hydroxide solution at 150° C., but if the amount of lead salt is halved and the temperature raised to 160° C., a microcrystalline red oxide is obtained (see also J. Chem. Soc., Jan., 1918).—W. G.

VIII.—GLASS; CERAMICS.

Potash suitable for glass making; Resources of— in the United Kingdom. P. G. H. Boswell. Soc. of Glass Technology, Dec. 19, 1917.

Up to the present no sources of soluble potash salts are available in the British Isles, to replace those previously obtained from Stassfurt and Alsace. Among available insoluble minerals may be mentioned felspar, mica, leucite, and glauconite. The most productive source is likely to be found in the various felspars, which are of wide occurrence. Granite cannot be used as a source of felspar as the latter is too small in grain to be picked out. Granite occurs up and down the country in huge masses, and often at the margins and scattered throughout the mass in veins is found felspar. Such veins are usually known as pegmatite and they may vary from 40 ft. in width to a few inches. Pegmatites are a valuable source of felspar, as

the latter is present in large, easily picked pieces, but they are only to be found in the most inaccessible spots—the North-West of Scotland, the North-West of Ireland, and in Cornwall.

The two chief varieties of felspar are known as microcline and orthoclase, and the latter is to be preferred as a source of potash as there is less tendency of this variety to form mixed crystals with soda felspar. Pegmatite consists of felspar and quartz in large pieces and must be hand-picked, the felspar being in crystals 3 to 4 inches long. Sometimes the felspar is intergrown with the quartz and the rock is then known as perthite. Felspar is prone to decomposition, brought about by gases and solution from below and by atmospheric action. The alkalis are leached out, leaving the silica and alumina as clay. When the leaching is effected from below the final product is very pure china clay. For pottery, felspar should be low in quartz, low in soda (to prevent crystallisation), and low in iron (to obtain good colour). The same features are necessary for glass-making and in addition there ought to be constancy of composition. Unfortunately this can never be realised. A potash content of 10 to 12% is desirable for glass-making felspar and the soda content should not be more than 3%, the iron content not more than 0.1%. All the British felspars are of the microcline type except the Roche deposit in Cornwall, which is orthoclase. The chief deposits in Scotland are in the vicinity of Loch Laxford, Durness, and Overseaig. In Ireland, felspar is found at Belleek, Belmullet, and Glenties, whilst good felsite is obtainable in Waterford and Wicklow, although its iron content is high. There seems little prospect of British felspar being placed on the market as cheaply as the pre-war Scandinavian supplies, owing to the cost of transport in this country and also the higher price and different conditions of labour.

Of late, many methods have been patented for the extraction and recovery of potash. It is hoped that a rich source of potash may be found in the flues of cement kilns and blast furnaces. Possibly it would be found expedient to increase the amount of potash in the flues of cement kilns by using felspar in the manufacture of cement.

W. G. Fearnside said that sedimentary rocks, being the disintegration products of igneous rocks (which all contain potash), might conceivably be a source of potash. Sands and limestones contain very little and so would not pay for extraction, but clays might very well do so.

C. J. Peddle pointed out that felspar was regarded by glass-makers as being important as much for the alumina as for the alkali it contained. It was a cheaper method of giving glass all the beneficial results conferred by alumina, than by using the calcined oxide, and was far more suitable than china clay for this purpose.

Silver films; Deposition of— on glass. A. Silverman and R. M. Howe. J. Ind. and Eng. Chem., 1917, 9, 1032—1035.

THE factors governing the deposition of silver on glass by the action of reducing agents on solutions of silver nitrate have been studied—the influence of temperature, time, concentration, and proportions of reagents on the quality of mirror and the quantitative efficiency of the deposition for a variety of reducing agents, namely, potassium tartrate, tartaric acid, lactose, sucrose, formaldehyde. The effect of the addition of alcohol was included. Working at high temperatures (80° C.) sucrose was found to give the best results. The tartrates are less satisfactory. For cold processes using formaldehyde as reducing agent, it was found that low concentration of this lengthened the time of deposition with advantage. Low concentration of the silver nitrate favoured high percentage depositions. The

addition of sugar controls the action of formaldehyde so as to produce uniform mirrors, and also retards the action. The addition of alcohol increases the efficiency of deposition. In view of these principles the following mixing is recommended for cold slow work: 16.5 c.c. of 0.037 molar silver nitrate, 1.0 c.c. of 1.0 molar sucrose, 0.5 c.c. of 80% methyl alcohol, 2.0 c.c. of 0.8% formaldehyde. After 40 minutes this deposits 20% of the silver present. For rapid cold work is recommended the addition of 0.5 c.c. of 40% formaldehyde to a mixture of 20 c.c. of 0.2 molar silver nitrate with 0.5 c.c. of 80% methyl alcohol. The results of cold deposition are superior owing to the greater temperature uniformity of reagents and glass and also because of the exclusion of temperature changes after deposition which, owing to different coefficients of expansion of glass and silver, cause a loosening of the mirror.—H. J. H.

PATENTS.

Crucible smelting furnaces [for glass]. C. M. Stein et Cie., Paris. Eng. Pat. 109,245, Nov. 24, 1916. (Appl. No. 16,891 of 1916.) Under Int. Conv., Aug. 29, 1916.

A CRUCIBLE smelting furnace, specially intended for glass or crystal melting. The regenerators are situated outside the main body of the furnace, and glass pits are provided in the base of the central burner and of the flues to protect the regenerators from contact with the glass. Removable plugs are fitted in the glass pits for cleaning purposes.—T. H. R.

Refractory composition [from slag from manufacture of ferrochromium]. F. M. Becket, Niagara Falls, N.Y., Assignor to Electro Metallurgical Co., New York. U.S. Pat. 1,244,688, Oct. 30, 1917. Date of appl., May 31, 1917.

Clay and other substances or articles; Process and apparatus for drying—F. A. Secord, St. John, New Brunswick, Canada. Eng. Pat. 111,166, Nov. 18, 1916. (Appl. No. 16,580 of 1916.) SEE U.S. Pat. 1,221,383 of 1917; this J., 1917, 551.

IX.—BUILDING MATERIALS.

Silica bricks; Manufacture of—H. Le Chatelier and B. Bogitch. Comptes rend., 1917, 165, 742—748. (See also this J., 1917, 963, 964.)

IN the manufacture of silica bricks it is the general practice to have present a certain proportion of large grains, sometimes up to 1 cm. in diameter. The object of these grains, it is considered, is to prevent the growth of cracks during firing, but as the grains themselves expand during the accompanying recrystallisation, they tend to exert a disruptive action which increases with the size of grain. For this reason a moderate limit should be set to the size, viz., 0.5 cm. On the other hand, a considerable proportion of impalpable powder is also necessary, whereby the recrystallisation of the quartz as tridymite from the viscous magma is accelerated. During the normal period of firing the solution and recrystallisation can only penetrate to a depth of about 0.01 mm.; hence grains greater than a 0.05 mm. mesh are practically inert and only those below 0.03 mm. are completely changed and are thus the most active in the production of the network frame of recrystallised tridymite in the brick. Exceedingly finely divided silica is necessary, then, to produce this network and in considerable proportion also if the network is to be so far developed as to ensure the stability of the brick at 1700° C. If 10% only of impalpable silica were present, then the lime (2% of the total silica) would represent 20% of this and would suffice to cause the whole of it to fuse at the high temperatures of steel furnaces. To confirm these views, experiments were made on the crushing strength at varying temperatures of bricks made up in different ways, with different proportions of coarse and fine grains and different grades of fineness. As impalpable silica the

No.	Mixture.	Linear dilatation. %	Density.		Crushing strength in kilos.			
			Apparent.	True.	Cold.		1600° C.	
					After drying.	Fired.		
1	75 raw quartzite 25 impalpable 2 lime	5.2	1.63	2.35	15	165	30

8	25 raw quartzite 75 impalpable 6 clay	5.2	1.43	2.36	9.5	160	6	
9	25 raw quartzite 75 fines 6 clay	—	—	2.34	7	55	2	
10	75 raw quartzite 25 impalpable 6 clay	5.0	1.50	2.34	19	110	16	

slimes from gold ore was used after purification with acid. As fine material were used the smaller particles (less than 0.1 mm.) resulting from breaking down a suitable quartz to 4 mm. size. The latter was used as the coarse raw material. The impalpable grains were of the order of 0.01 mm. in diameter. The bricks were fired 5 days up to cone 19.

The crushing strengths are in kilos. per sq. cm., and the values at 1600° C. are those necessary to crush after 1 hour's heating at that temperature. The results (Nos. 1—4) show the value of admixture of impalpable silica (25%) in increasing the mechanical strength at furnace temperatures. Similar experiments made with a quartz, not so easily transformed in baking, gave a like result when impalpable silica was incorporated. At the same time it was observed that although pressing increased the strength of the bricks when cold, no advantage was apparent at 1600° C. when compared with hand-made bricks of the same mixture. Experiments (Nos. 5 and 6) made, using quartzite which had been fired in place of the same in the unfired state, showed that where the quartz has undergone a preliminary transformation, it still gives a brick satisfactory at 1600° C., although decidedly inferior to those made from the raw quartz. Where the quartz is readily transformed, there is then no advantage in baking the raw material before manufacture. Experiments made when the 2 parts of lime was replaced by 6 parts of clay containing 2 parts of bases (alumina, iron and potash), showed that the product was inferior to that made with lime (experiments 7—10). These bricks differed also in suffering a progressive deformation under load at 1600° C. instead of a sudden collapse characteristic of bricks with the lime binder. It is concluded that the best composition is 75% of coarse quartz, 25% of impalpable quartz—grain size as given, bound with 2% of lime.—H. J. H.

Potash; Recovery of— as by-product of the cement industry. W. H. Ross and A. R. Merz. J. Ind. and Eng. Chem., 1917, 9, 1035—1038. (See this J., 1917, 612.)

THE process described previously has been applied to the flue dust from cement kilns. The potash present can be liberated and volatilised completely by heating feldspar mixed with lime for 1 hour, on a laboratory scale. A similar reaction takes place in the cement kiln between the constituents of the charge containing lime and potash, and a greater or less proportion of the latter is volatilised, appearing in the flue dust. This, when fresh, consists of sulphates, sulphides, and chlorides of potash, soda, and lime. The proportion of sulphides is greater in oil- or gas-fired kilns. Free lime is present and the extract is alkaline. Analyses of the raw mix and cement clinker from 113 works in America permitted an estimation of the amount of potash recoverable. The raw mix contained from 0.2% to 1.16% of K_2O and the analyses showed that the weight of potash volatilised per barrel of cement varied from 0.35 to 5.34 lb. Omitting plants using blast-furnace slag, the average of 99 plants was 2.09 lb., which means an annual production for the United States of about 87,000 tons of K_2O volatilised. By electrical precipitation (Cottrell process) 99% of the flue dust can be precipitated, but as the lighter portions are richer in potash, only 90% of the potash is thus recoverable, i.e., 78,000 tons on the above basis. When the kilns are coal-fired, the proportion of soluble potash in the dust is lowered—59.6% in one case, against 91.6% in an oil-fired kiln. Laboratory experiments show that the process described above—digestion with lime water under pressure—renders 90% of the potash soluble in 4 hours at 100 lb. pressure and 95% after 8 hours. Assuming a 90% yield of soluble potash, the

annual production would be 70,000 tons or, excluding plants volatilising less than 1 lb. K_2O per barrel, 67,000 tons. This however could be materially increased by increasing the proportion of potash in the raw mix. Where aluminiferous cements are made, feldspar alone can be added, whilst for silicious cements, feldspar and a suitable proportion of iron ore would be necessary. In one case the proportion of K_2O volatilised was increased from 38% to 65% by the addition of salt to the raw mix. The percentage of total alkali in the finished cement was thereby reduced. In another works calcium fluoride was used and the potash driven off as potassium fluoride. On leaching the dust with hot water the calcium and potassium compounds reacted, regenerating the calcium fluoride in the insoluble residue and leaving the potash in solution as sulphate or carbonate. The insoluble residue was returned to the furnace and in this way the proportion of potash volatilised was increased from 60% to 90%. In some works the proportion of potash volatilised can be increased by raising the temperature of the kiln. The percentage volatilisation varies from 25% to 96% and it is considered that by rational working the lower figures could be much increased. If an average yield of soluble potash equal to about 50% could be attained—and experience shows this is possible—then an annual production of 100,000 tons of K_2O could be realised. The treatment of cement flue dust by electrical precipitation and recovery of soluble potash is being rapidly extended in American plants.—H. J. H.

Reinforced concrete: Deteriorating action of salt and brine on—. H. J. M. Creighton. J. Franklin Inst., 1917, 184, 689—704.

THE author emphasises the injurious action of salt solutions, especially of chlorides, on cement, and indicates the special danger to concrete reinforced with iron. In contact with brine the latter becomes converted into oxides of iron either by local electrolytic action or otherwise, for the concrete in practice is never completely impervious to air and water. The oxides or hydroxides of iron are more voluminous than the corresponding metallic iron and therefore exert a powerful disruptive action on the concrete in which the iron is embedded. The effects of this are illustrated by 10 photographs of reinforced concrete structures which have suffered owing to the rusting of the iron skeleton. In all cases the concrete had been exposed to the action of brine. The course of the deterioration is as follows: The concrete develops cracks with iron-coloured stains parallel to the reinforcements; the cracks widen and lengthen until a layer of concrete falls away, baring the iron below.—H. J. H.

X.—METALS; METALLURGY, INCLUDING ELECTRO-METALLURGY.

Pig iron; Electric—in ear-times. R. Turnbull. Amer. Electrochem. Soc., Oct., 1917. [Advance copy.] 5 pages.

THE recent high prices of pig iron have failed to stimulate its production from ore in electric furnaces. This is attributed mainly to the shortage of power, and not to the inherent difficulties of the process. No advantage is found in the use of shaft furnaces as compared with the ordinary types of electric furnace. The war, however, has given an impulse to the manufacture of pig iron from shell scrap and turnings in electric furnaces, and owing to the purity of the scrap, a product of high quality is obtained without much refining. The principal feature is its low phosphorus content. And account is given of the working of a 6-ton furnace in Canada. It is said that in the United

States steel turnings are being added with the ore charged into blast furnaces. The author doubts whether these processes will be feasible generally after the war, but regards them as possible in Canada. Attention is drawn to the importance of correct fit of the coolers placed (round the electrodes) on the roofs of electric furnaces. The coolers should be cast to the exact form of the brickwork, on which they should rest without intervening packing. This is to ensure uniformity of cooling effect over the whole of the brickwork, whereby its life is materially prolonged.—H. J. H.

Electric furnace: The — in the Norwegian iron industry. H. Styri. Amer. Electrochem. Soc., Oct., 1917. [Advance copy.] 11 pages.

IN Norway high-grade charcoal irons were formerly manufactured, but the industry declined during the nineteenth century. From 1909 onwards a number of attempts were made to smelt pig iron in electric furnaces, but with only limited success. Such plants as were working at the commencement of the war have been very successful owing to the failure of imported supplies of pig iron. None of these concerns has converted the latter into steel, but—especially since the outbreak of war—a number of plants have melted steel scrap and manufactured special steels of various kinds. The Rennerfelt type of furnace is most commonly employed, but the author considers that it shows no marked advantages over the Héroult furnace. In late years a strong desire has been evident in Norway to make the country more self-supporting in the matter of steels for general purposes, and the war has accentuated this feeling. The Government has helped in the establishment of steel plant—open-hearth and Tropenas converter furnaces—to meet this want. The prospects of a steel industry are discussed. Coal is not plentiful and is remotely placed near the Russian border. Spitzbergen coal is good for steam raising but poor for coking. Iron ores are generally of low grade and remotely placed. It is considered that the future of structural steels made by the older processes is very doubtful and that the prospects are best for electric furnace products—made from scrap and perhaps from ore—which should command a market owing to their high grade.—H. J. H.

Pure [iron] alloys; Preparation of — for magnetic purposes. T. D. Yensen. Amer. Electrochem. Soc., Oct., 1917. [Advance copy.] 18 pages.

THE elimination of impurities has a marked beneficial effect on the magnetic permeability and hysteresis loss of iron. It is considered that the magnetic properties at low and medium flux densities depend largely on the thickness and quantity of the intercrystalline material. It is known that a joint reduces the permeability of two contiguous pieces of iron enormously. Carbon, phosphorus, and sulphur are usually present in iron as the corresponding compounds of iron, at the boundaries of adjacent grains of ferrite, and these compounds are known to possess low permeabilities. Where these compounds are practically absent very high permeabilities may be attained. Elements like silicon and aluminium, which are present in the iron in solid solution, do not materially affect the permeability but increase the resistance. At high flux densities all additions, except nickel and cobalt, lower the permeability: cobalt up to 34.5% increases the saturation capacity. The most reliable sources and methods of preparation of pure metals are tabulated. Electrolytic iron prepared by the method of Burgess (this J., 1904, 667) and cobalt by the method of Kuhnau (this J., 1914, 261) are recommended. The metals and alloys are melted in crucibles made of magnesite which has been calcined at 1000 C., fused in an air furnace, ground to pass a 20-mesh sieve, bound with

magnesium hydroxide, and pressed to shape in steel moulds under 25 tons pressure. Electric furnaces with inert atmosphere or working under a vacuum are used. The resulting alloys may be worked or forged, but if so they should be annealed again, as this conduces to growth of crystal grain which favours increased permeability.—H. J. H.

Manganese and some special manganese steels; Magnetic properties of —. R. Hadfield, C. Chéneveau, and C. Gèneau. Roy. Soc. Proc., 1917, A, 94, 65—87.

THE relation between the magnetic susceptibility of manganese and manganese steels and their chemical constitution was investigated by means of a Curie and Chéneveau magnetic torsion balance, in which the metal is suspended from a torsion wire and a permanent horseshoe magnet is moved horizontally in a direction at right angles to the line joining the poles so as to vary the field. Anhydrous cobalt sulphate having a mass susceptibility of $+58 \times 10^{-6}$ at 20° C. was used as a standard of comparison, and magnetic fields of 320 and 1600 gauss were used. The samples were enclosed in thin-walled glass tubes, the effect of which was negligible, and the effect of temperature variations was also found to be comparatively small. Powdered manganese was found to be paramagnetic and to have a mean mass susceptibility of 11.0×10^{-6} . Cast manganese was found to be ferromagnetic, but after repeated heating to redness and washing with hydrochloric acid, the mass susceptibility gradually fell from 2000×10^{-6} , approaching the value for powdered manganese. The ferromagnetic properties were inferred to be due to occluded hydrogen. Manganese steels gave variable and large values which were greatly reduced after washing with hydrochloric acid to remove surface ferri-ferrous impurities, to the order of 75 to 100×10^{-6} . The size of the specimen was found to be immaterial provided the specimen is small, and curves are given showing the effect of varying the relative position of the magnet and the specimen. The presence of manganese has little effect on the magnetic properties of steel; the susceptibility increases with the addition of nickel, copper, chromium, or tungsten, but decreases with the addition of carbon, while silicon makes steel ferromagnetic.—W. F. F.

Copper tailings; Ammonia leaching of — at Kennecott, Alaska. H. M. Lawrence. Eng. and Min. J., 1917, 104, 781—787.

THE ores of the Bonanza and Jumbo mines consist of chalcocite, malachite, and azurite in a gangue of grey limestone and dolomite; the proportion of carbonate ore averages 36% of the copper value. The ore is hand-sorted to separate larger pieces of sulphide and carbonate from the poorer material, which is concentrated on jigs and tables; 95% of the sulphide and 60% of the carbonate values are thus recovered. The tailings are treated in the leaching plant (this J., 1917, 966) which has a daily capacity of 300 tons of tailings. The ammoniacal solution in contact with the ore is converted into carbonate, which, however, extracts the copper satisfactorily. The exhausted charge is washed with steam. The solvent is recovered by distillation in evaporators operated intermittently, during which a precipitate containing 70% Cu is obtained; continuous distillation was abandoned owing to clogging and formation of incrustations. The extraction averages 75% of the carbonate copper. The losses of ammonia are stated to be $\frac{1}{2}$ lb. per ton leached. An 800-ton plant is in course of construction.—W. R. S.

[Copper;] *Recent developments in connection with the use of sulphur dioxide in hydrometallurgy [of —].* E. R. Weidlein. J. Ind. and Eng. Chem., 1917, 9, 1057—1058.

AT the experimental 5-ton plant at Thompson,

Nev., carbonate or roasted sulphide ores are leached with sulphuric acid. The solution is neutralised with lime, treated with sulphur dioxide, and heated to 100° C. under a pressure of 100 lb., when metallic copper is precipitated. After remelting it is over 99% pure, the balance being chiefly oxygen. Solution and precipitation are continuous. The plant was started in April, 1916, and is being enlarged.—W. R. S.

Copper converting; Development of — M. W. Krejci. Eng. and Min. J., 1917, 104, 669—674.

THE Manhès converter, invented in 1880, was introduced at the Parrot smelter, Butte, in 1883-t. Two types were subsequently evolved: the vertical or Great Falls, and the horizontal or Peirce-Smith type. Tilting was first done by hydraulic power, but this has been almost supplanted by electricity. Converters were originally lined with quartz and clay, the lining combining with ferrous oxide formed by the oxidation of the matte. In later practice silicious ore was thrown into the converter to prolong the life of the lining. In 1910 the magnesite or basic lining was adopted. The lining takes no part in the converting reactions, all the silica being added in the form of ore either through the mouth or the tuyères. At the Great Falls smelter, new magnesite linings used to be first coated with matte by blowing it without silica for a few minutes, and cooling. It was found that the lining so obtained consisted largely of magnetite and was far superior to magnesite as regards resistance to corrosion. This coating is now in regular use, and with proper care the magnesite lining lasts almost indefinitely; the magnetite coating is patched when required, generally once in several months.—W. R. S.

[Zinc] blende-roasting furnace; Choice of a — M. F. Chase. Eng. and Min. J., 1917, 104, 698—704.

THE first cost and the working cost of a furnace are of less importance than its ability to produce a roasted ore low in sulphur and free from lumps, and a uniform gas high in sulphur dioxide and poor in dust. The furnace should satisfy the following conditions: (1) the ore must be rabbled continuously; (2) the arches must be low, to ensure thorough removal of sulphur dioxide; (3) the ore must not fall through the ascending gas current; (4) the temperature of the different hearths must be controlled by regulating the air supply; (5) the air must be preheated by passing it over the roasted ore; and (6) the rabbles must be easily accessible for repairs. As no furnace fully fills these conditions and the available data on operating conditions are often unreliable, the installation of the best type of furnace to suit local conditions is largely a matter for experiment. The continuous rabble muffle furnaces (such as the Ridge, Wedge, and Huntington-Heberlein) have decided advantages over other types, since the difficulty of cooling the rabble arms while maintaining the heat of the furnace has been overcome; future improvements will probably take place along the lines developed in these furnaces.—W. R. S.

Zinc-oxide furnaces. J. F. Cregan. Eng. and Min. J., 1917, 104, 675—680.

THE furnaces in use are of two distinct types: the Eastern, used chiefly at Palmerton, Pa.; and the Western (Rocky Mountains, etc.). The former consists of a series of (generally six) individual grates leading into a common flue, but controlled separately as regards blast pressure and exhaust. Each grate may be shut off from the main flue at any time. The Western furnace has 8—16 double grates and a main flue under one common arch; the grates have secondary arches and are

separated from each other by side walls, but the exhaust pressure can only be regulated on the furnace as a whole. In furnaces of the Western type, the weight of ore charged is 80—120 lb. per sq. ft. of grate surface; this is mixed with 80—100% of coal, and 10—90% of flux if required. The entire charge is intimately mixed before charging, and is fired for 8 hours. The clinker is removed, and the next charge introduced. The zinc content of the clinker is as low as 1% at certain plants, but much higher in general practice. In the author's opinion the Western furnace is of greater adaptability to varied ores and fluxes.

—W. R. S.

Brass rolling mill alloys. R. A. Wood. J. Amer. Inst. Metals, 1917, 11, 181—192.

ANTIMONY and bismuth are most harmful in rolling; the effect of arsenic is much less pronounced. The fuel used for melting down should be as low in sulphur as possible, for copper and its alloys absorb sulphur dioxide and become brittle; the metal should be covered with charcoal during the melting. An alloy containing equal parts of copper and zinc is used for brazing; it can still be rolled or drawn, but the operation is most tedious. Brasses with 57—63% of copper (Muntz metal) are used in the extruding process. Those containing more than 60% of copper can be worked cold. Lead (0.5—4%) is added to brass to facilitate milling, turning, or drilling; it diminishes the cohesion of the metal. Tin produces a close-grained brass of high tensile strength. The trade name "tin-bronze" is given to copper-tin alloys free from zinc; a small amount of phosphorus greatly facilitates casting, and the alloys are then termed phosphor-bronzes. Many manufacturers state that phosphorus in alloys containing zinc produces fine pinholes in the castings, but others consider 0.05% beneficial. Very high tensile strength and density of grain are attained by the addition of iron (0.25—2%); it has a tendency to segregate in small hard nodules; manganese assists in distributing the iron. Brasses to which both tin (0.25—5%) and lead 0.5—3% have been added are free-turning, close-grained and take a high finish. Nickel (2—32%) is used in cutlery and hard spring metal, the usual copper-zinc ratio being 2.5:1; iron (0.5—2%) hardens these alloys considerably. Cupronickel (nickel 5—25%) must be cast at a very high heat, particularly that containing high percentages of nickel. Addition of manganese to cupronickel produces alloys of high electrical resistance.

—W. R. S.

Antimony; Production of electrolytic — from impure ores. W. A. Burr. Eng. and Min. J., 1917, 104, 789—790.

THE tests were carried out in a plant capable of producing 1000 lb. of metal per day. The stibnite ore was crushed to pass an 8-mesh sieve in the solvent solution (7% sodium hydroxide and 2% sodium chloride), and the pulp leached in two Douglas fir tanks (diameter 16 ft.), the filter-bottom of which supported one thickness of cocoa matting covered with a seamless woollen filter cloth. The solution, heated with steam to 60° C., was let in beneath the filter-bottom, overflowing into the pregnant-solution tank from which it was decanted into wooden precipitation cells measuring 2½ × 2½ × 15 ft. Each cell contained 80 mild steel sheet electrodes. A current density of 8—9 amp. per sq. ft. of cathode surface, at a tension of 2.25—2.50 volts, gave a coarse crystalline deposit which was scraped off when it had accumulated to ¾ in. on both sides of the cathodes. The precipitate was washed, dried, melted down, and cast into ingots assaying 99.94% Sb. The sulphur in the foul liquors was removed from time to time by carbon dioxide.

The cost of production was 2.2 cents per lb. of "star" metal.—W. R. S.

Flotation; Chemicals used in ore —. O. C. Ralston and L. D. Yundt, J. Ind. and Eng. Chem., 1917, 9, 1058—1062.

THE use of flotation agents other than oils is discussed. Sulphuric acid often produces a cleaner froth and an increase in extraction, and sometimes allows of reduction in the proportion of oil used. The cause of the improvement is unknown. With certain partly oxidised copper ores, acid is fatal to good flotation. Copper sulphate (1 lb. per ton of ore) has caused higher recoveries of zinc blende in many cases, though not invariably. Probably the blende particles become coated with copper sulphide, but the reason why the filmed particles float better is not known. Sodium carbonate or hydroxide is used in many mills, but beyond the fact that the results are improved, very few observations on their mode of action have been reported. Sodium silicate and sulphide are also employed. The last named acts by coating oxide ores with a film of sulphide (this J., 1917, 460). Lime is not so desirable as sodium compounds; unlike the latter, it usually flocculates the gangue slime. Tartaric and citric acids are mentioned in Eng. Pat. 17,327 of 1914 (this J., 1915, 910); 0.1 to 0.25 lb. of argol per ton of ore has been used with success on copper ores containing much clayey matter. The use of silicofluorides is claimed in Eng. Pat. 4938 of 1914 (this J., 1915, 431) as a substitute for acids. Sodium manganate and chromate are recommended for differential flotation; they could be made cheaply by fusing local manganese or chromium ores with soda. Sulphur dioxide, and sodium sulphate or thio-sulphate in sufficient amounts inhibit flotation. Chloride of lime is said to effect differential flotation of blende from pyrites. Sodium cyanide has been found deleterious to flotation in most cyanide mills in which tailings have been tested. —W. R. S.

Flotation concentrates; Vacuum filtration of —. R. R. Woolley, Eng. and Min. J., 1917, 104, 875—877.

UP to the present, the most successful method of de-watering flotation concentrates has been vacuum filtration. The pulp is settled in Dorr thickeners and pumped into filter troughs from which it passes into continuous-vacuum filters. Since the drying of the cake is caused by the air passing through it, the amount of the latter must be regulated so as to build a cake and permit the greatest volume of air to pass through it at the least cost. To determine this requires experiment in each individual case. Usually the pumps are designed to pass 0.5 to 1 cub. ft. of air per minute for each sq. ft. of filter surface. The filtering medium used must be adapted to the character of the pulp. With fine compact material the best results are obtained with light twill; with loose granular concentrates, duck-cloth is required. Smaller particles of ore have a greater relative area, hence the amount of moisture remaining in the cake increases as the size of the particles decreases.—W. R. S.

PATENTS.

Steel ingots; Casting —. Sir W. G. Armstrong, Whitworth and Co., and H. H. Ashdown, Newcastle-upon-Tyne, Eng. Pat. 111,133, Nov. 10, 1916. (Appl. No. 16,112 of 1916.)

To prevent segregation and formation of corner cracks, the sides of the ingot, and the bottom from the base upwards, are cooled during pouring. In the sides of the mould and in the bottom plate are pipes for the circulation of the cooling medium,

so arranged that the bottom plate, or any section of the mould, can be cooled as desired.—T. H. B.

Engraved steel or other intaglio plate; Method of reproducing an — and an intaglio printing plate produced by said method. R. W. Barker, London. From American Bank Note Co., New York. Eng. Pat. 111,164, Nov. 17, 1916. (Appl. No. 16,525 of 1916.)

A CAMEO matrix of ductile metal such as lead is formed by hydraulic pressure from an original plate bearing a design formed of a number of shallow depressed lines. Iron or steel is deposited upon this matrix used as a cathode in an electrolyte of iron sulphate solution containing about 1% of vanadium chloride, and having a density of at least 21° B. and preferably at a temperature of 160° F.; nickel sulphate or nickel ammonium sulphate may be used instead of vanadium chloride. A thin coating of copper on the matrix before deposition of the iron produces a better printing surface; the matrix is rotated slowly and is cleared from liberated hydrogen by mechanical means or by reversal of current, and precipitated oxides are removed by constant circulation of the electrolyte through a filter, the salts thus lost being replaced by fresh solution; finally, the matrix is stripped from the deposited plate and the iron or steel hardened or tempered.—T. H. B.

Electric [induction] metallurgical furnaces. A. Turner, Greenock. Eng. Pat. 111,120, Aug. 16, 1916. (Appl. No. 11,564 of 1916.)

FOR the direct reduction of iron and steel from the ore, with evolution of cyanogen in the gases, and its fixation in the lime slags, three furnaces are used, two of the reverberatory type, the other a cupola of the retort type. The latter is in the middle, the others on each side of it, one under the base of the cupola hearth, the other on the cupola scaffold, forming a reservoir of any desired capacity, and all the furnaces are connected by channel-ways for fluid molten iron. The cupola has a circular channel, either inside or outside of it, and the channel has branch gates leading in pairs into the shaft of the cupola; beneath these paired gates and the refractory lining, horse-shoe electro-magnets are placed so that each gate has a limb of the magnet beneath it. The production of cyanogen in the reduction of the charge is accelerated by the action of the air which is drawn through the tuyères by the gravitational action of the falling, electrically charged molten iron. The cyanogen is conducted, by means of pipes, from the cupola hearth, over the lime-iron ore fluxes in the reverberatory furnaces. When cyanamide is desired, carbide-producing material is used as a flux.—T. H. B.

Ores and the like; Dressing —. W. Mauss, Johannesburg, Transvaal. Eng. Pat. 111,377, Jan. 10, 1917. (Appl. No. 499 of 1917.)

CRYSTALLINE and colloid constituents in ore pulp, mixed with water, are separated from each other by a centrifugal force, not less than fifty times, and usually from one to two hundred times greater than that of gravity.—T. H. B.

Ferro-phosphorus; Process for producing —. J. J. Gray, Rockdale, Tenn., U.S.A. Eng. Pat. 111,385, Jan. 19, 1917. (Appl. No. 987 of 1917.)

SEE U.S. Pat. 1,220,416 of 1917; this J., 1917, 555. The requisite high temperature in the fusion zone is maintained by using a blast of air preheated to at least 900° F. (480° C.).

Zinc smelter; Continuous —. W. McA. Johnson, Hartford, Conn. U.S. Pat. 1,244,504, Oct. 30, 1917. Date of appl., Feb. 4, 1915.

AN electric furnace is connected with a con-

denser and with a preheating retort. Granulated material to be smelted is fed into the preheating retort which is heated externally by means of a fuel-fired furnace, and the charge then falls through a drop shoot which hermetically connects the retort and electric furnace. The whole of the gases from the electric furnace pass to the condenser.—T. H. B.

[Alloy.] *Composition of matter.* C. L. Jones, Oakland, N.J., Assignor to F. J. Molt, Riverdale, N.J. U.S. Pat. 1,241,742, Oct. 30, 1917. Date of appl., Feb. 8, 1917.

AN alloy of Ni (67.8%), Cu (28.0%), Mn (2.5%), Fe (1.5%), V (0.2%), with or without carbon.—T. H. B.

Alloy. F. M. Becket, Assignor to Electro Metallurgical Co., Niagara Falls, N.Y. U.S. Pat. 1,245,552, Nov. 6, 1917. Date of appl., Apr. 10, 1916.

AN alloy which is tough, hard, and resistant to oxidation, consists of Cr 20—35 (25 to 30) %, C 1.5 to 3.0 %, Si nil to 3.0 %, the remainder being principally iron.—T. H. B.

Copper ores; Process for the treatment of —. G. C. Westby, Ludwig, Nev., Assignor to Western Process Co. U.S. Pat. 1,244,810, Oct. 30, 1917. Date of appl., Aug. 17, 1915.

OXIDISED copper ore is wetted and subjected to the action of gaseous sulphatising reagents, the resulting sulphates are leached out and treated with metallic iron, and the precipitated metals removed. The solvent is removed and the residue dried and calcined to form a pigment and acid gases, the latter being used again for sulphatising.—T. H. B.

Ores; Process for the treatment of —. G. C. Westby, Ludwig, Nev., Assignor to Western Process Co. U.S. Pat. 1,244,811, Oct. 30, 1917. Date of appl., Jan. 12, 1917.

ORE mixtures containing sulphide are treated in an enclosed space with a descending current of a solution of acid nitrate, while a counter current of sulphur dioxide and oxygen regenerates nitric and sulphuric acids. The solution is used repeatedly until the ore body is exhausted, and is then passed through a mass of cleaned sulphide to liberate nitrous gases, which are oxidised and used again.—T. H. B.

Sintering (flue-dust, etc.); Process of —. A. J. Boynton, Lorain, and A. E. Sands, Akron, Ohio. U.S. Pat. 1,245,183, Nov. 6, 1917. Date of appl., Aug. 3, 1917.

FLUE-DUST or other similar combustible material is sintered by forming it into a bed on a porous hearth, igniting the upper horizontal face of the bed, and drawing air through it vertically downwards; the bed is tilted to drain off molten cinder formed during the sintering operation.

Open-hearth furnace. T. S. Blair, jun., Chicago, Ill., Assignor to Blair Engineering Co., New York. U.S. Pat. 1,245,555, Nov. 6, 1917. Date of appl., July 20, 1917.

THE upper part of the end wall of the gas down-take has a chrome ore facing, immediately below the entrance of the gas port; sections of the facing rest on a series of water-cooled shelves which keep them in position.—T. H. B.

Metallurgical filtration; Method of —. P. A. Boeck, Assignor to Celite Products Co., Los Angeles, Cal. U.S. Pat. 1,245,557, Nov. 6, 1917. Date of appl., Nov. 3, 1914.

A MIXTURE of divided ore and divided inert porous mineral matter (e.g., kieselguhr) is treated with a leaching liquid and then filtered.—T. H. B.

Blast furnaces; Water circulation of tuyères and coolers of —. W. J. Foster, Walsall, Eng. Pat. 111,199, Jan. 17, 1917. (Appl. No. 845 of 1917.)

Atomising metals in a state of fusion; Process for —. F. C. Ucar, Madrid. U.S. Pat. 1,245,536, Nov. 6, 1917. Date of appl., July 6, 1915.

SEE Eng. Pat. 2413 of 1915; this J., 1916, 425.

Burnt pyrites and the like; Method for treating [chloridising] —. E. R. Sutcliffe, Leigh. U.S. Pat. 1,245,631, Nov. 6, 1917. Date of appl., July 11, 1913.

SEE Eng. Pat. 16,450 of 1912; this J., 1913, 1115.

Refractory composition [from slag from manufacture of ferrochromium]. U.S. Pat. 1,244,688. See VIII.

Insecticidal composition [from smelter fume dust]. U.S. Pat. 1,244,453. See XIXB.

XI.—ELECTRO-CHEMISTRY.

PATENT.

Electric furnaces [; Temperature-controlling device for —]. C. E. Hearson, London. Eng. Pat. 111,207, Feb. 1, 1917. (Appl. No. 1661 of 1917.)

IN a tubular electric resistance furnace designed to be operated at say 700°—800° C., the furnace chamber proper, which may be of silica glass, is enclosed in an outer brass tube which acts as a thermostatic element and is connected at each end to slabs of poor conducting and good fire-resisting material, the slab at one end being free to move away from or towards the slab at the other end as the brass tube expands or contracts. A light steel rod is supported between the end slabs outside the furnace and is connected with a lever in such a way that the variations in the expansion and contraction of the brass tube operate spring contact devices for breaking and making the heating current circuit and so regulate the temperature of the furnace.

XII.—FATS; OILS; WAXES.

Emulsions; Stability of — in the constricted tube and marble device for anaërobiosis. I. C. Hall. J. Phys. Chem., 1917, 21, 609—622.

IN the cultivation of anaërobic bacteria in a constricted tube with a seal of hydrocarbon oil, in which a marble was placed, it was found that when the tube was heated in boiling water and then cooled, the oil below the marble became opaque owing to the formation of a fairly stable emulsion with the water. Emulsions may be prepared in this way with water and various petroleum oils, chloroform, ether, benzene, xylene, carbon bisulphide, olive oil, and aniline. The stability of such emulsions when formed in an open tube by rapid cooling in ice water, is slight as compared with similar emulsions formed below a marble seal, e.g., in the case of water and olive oil less than one day as compared with more than 61 days below the seal. The presence or absence of an air surface above the emulsion does not affect the stability, but a marble or other mechanical seal interferes with diffusion and thus prevents evaporation, and to this must be attributed the relatively greater stability of emulsions formed below such a seal.—C. A. M.

PATENTS.

Drying oil; Vegetable — [and cattle food]. S. Loamnitz, Merida, Mexico, Assignor to J. Joffe, New York. U.S. Pat. 1,244,521, Oct. 30, 1917. Date of appl., Feb. 17, 1916.

A DRYING oil is obtained from the seeds of the

chia plant of the genus *Salvia*, family *Labiatae*, whilst the residue forms a cattle food.—C. A. M.

Seeds and nuts; Process of treating — for obtaining oil and other products [tannin]. B. Loomis, Assignor to Burdett Loomis Corporation, Hartford, Conn. U.S. Pat. 1,241,995, Oct. 30, 1917. Date of appl., May 5, 1915.

Hot water and an acid solvent, such as acetic acid, are made to circulate at a temperature between 100° and 170° F. (38° and 74° C.) through the oil-bearing material in a closed tank and the resulting extract of tannin drawn off. The residual material is then treated with water and the acid solvent at an increased temperature to remove oil, waxes, gums, etc., and the extract drawn off into a separating chamber, whilst the residue is subjected to the action of a circulating current of gas at a gradually increasing temperature until free from ammonia or other volatile matter, and is then dried.—C. A. M.

XIII.—PAINTS; PIGMENTS; VARNISHES; RESINS.

Some compounds of lead. [Preparation of red lead.] Zotier. See VII.

PATENTS.

Pigments. L. G. Hill, Birmingham, Eng. Pat. 111,318, Nov. 16, 1916. (Appl. No. 16,121 of 1916.)

ANY clay, rock, ore, mark, or the like, free from carbonates, and containing not less than 25% of metallic oxides, of which 80% is aluminium oxide, is deprived of a portion or all of its silicious constituent by means of hot caustic soda solution. For example, china clay is heated under pressure in a strong solution of caustic soda. The undissolved residue when washed and dried is suitable for use as a pigment.—E. W. L.

Kauri and other like gums; Process for the treatment of —. F. V. Raymond, Auckland, N.Z. U.S. Pat. 1,245,273, Nov. 6, 1917. Date of appl., Sept. 6, 1916.

KAURI and other like gums are treated by means of sand blasts, water blasts, and drying blasts, operated by compressed air.—E. W. L.

Resinous compound; Halogenated —. J. P. A. McCoy, Wilkinsburg, Pa., Assignor to Westinghouse Electric and Manufacturing Co. U.S. Pat. 1,245,363, Nov. 6, 1917. Date of appl., Feb. 3, 1916.

A HALOGEN (chlorine) di-substitution product of a resinous coal-tar derivative, containing cumarone, indene, para-cumarone, and/or para-indene, is prepared by passing gaseous chlorine for about 8 hours through a melted coal-tar derivative containing at least one of the above-named substances.—E. W. L.

Process for the treatment of copper ores. U.S. Pat. 1,244,810. See X.

XIV.—INDIA-RUBBER; GUTTA-PERCHA.

PATENTS.

India-rubber later; Apparatus for and process of estimating the volume of acid required to coagulate a given volume of —. T. Cockerill, Colombo, Ceylon, Eng. Pat. 100,591, May 27, 1916. (Appl. No. 7511 of 1916.) Under Int. Conv., May 29, 1915.

The stem of a metal hydrometer of special design is so graduated that, either directly, or by

reference to tables, any of the following values for a given sample of latex into which the hydrometer is introduced may be read off:—specific gravity, ounces of wet rubber per gallon of latex, volume of glacial acetic acid required for coagulation, volume of 4% acetic acid required for coagulation.—E. W. L.

Product possessing rubber-like properties. C. Weygang, Maidenhead, Eng. Pat. 111,171, Nov. 22, 1916. (Appl. No. 16,733 of 1916.)

CASEIN or animal glue is digested with carbolic acid or acetic acid at a temperature not exceeding 180° F. (82° C.) until complete solution is effected. Mineral substances such as zinc oxide, zinc carbonate, or calcium hydroxide, and organic substances, such as glycerin, molten pitch, or solutions of resins or of rubber or celluloid may then be added, and the mixture is treated with formaldehyde, formic acid, or tannic acid with energetic mixing until the whole is converted into a tenacious rubber-like mass. If much pitch is used the product may be sufficiently insoluble without the subsequent treatment with formaldehyde or formic or tannic acid. (Reference is directed in pursuance of Sect. 7, Sub-sect. 4, of the Patents and Designs Act, 1907, to Eng. Pats. 4343 of 1874, 18,861 of 1896, 15,115 of 1898, 926 of 1901, 27,090 of 1901, 12,277 and 12,278 of 1905, 23,031 of 1907, 4151 and 18,691 of 1909, 26,093 of 1910, and 17,242 of 1914; this J., 1897, 749; 1898, 933; 1905, 812; 1906, 327; 1908, 1075; 1910, 100, 911; 1911, 1398; 1916, 266.)—D. F. T.

Rubber products; Manufacture of —. L. E. Barton, New York, and H. A. Gardner, Washington, U.S.A. Eng. Pat. 111,257, June 29, 1917. (Appl. No. 9121 of 1917.) Under Int. Conv., Jan. 2, 1917.

TITANIUM dioxide is applied as a "filler" for rubber, the advantages claimed in the resulting mixing including increased strength and rapidity of vulcanisation whilst the oxide also has exceptional colouring power and is capable of giving remarkably white products. For the production of a vulcanised rubber showing great toughness and therefore applicable to the formation of automobile tyre treads, a mixing of titanium dioxide 450, sulphur 50, and washed rubber 500 parts is recommended. The titanium dioxide need not be pure and can be used with excellent results in the form of "composite titanic oxide pigments" (see this J., 1915 1104; 1917, 91, 604.)—D. F. T.

Rubber; Compounding of —. W. C. Geer, Akron, Ohio, Assignor to B. F. Goodrich Co., New York, U.S. Pat. 1,245,700, Nov. 6, 1917. Date of appl., May 26, 1916.

IN order to mix fine powder, such as gas-black, with rubber in a mixing mill, the powder is first moistened, e.g., with kerosene oil, and brought into a dustless, granular condition.—E. W. L.

XV.—LEATHER; BONE; HORN; GLUE.

PATENTS.

Tanning [with iron salts]; Processes for —. O. Röhm, Darmstadt, Germany, Eng. Pat. 103,827, Jan. 25, 1917. (Appl. No. 1259 of 1917.) Under Int. Conv., Jan. 28, 1916.

SATISFACTORY tanning may be effected with iron salts when the skins are treated either previously or simultaneously with an aldehyde such as formaldehyde. Example: 100 parts of unhaired hides is tanned for 1–2 hours with 200 of water containing 3 of 40% formaldehyde solution and 2 of a sodium bicarbonate. The hides are washed and tanned in a solution of 20 parts of iron chloride

in 150 of water rendered basic by the addition of 1 part of sodium carbonate. After tanning, the leather is washed and neutralised in the same way as chrome leather. If desired the iron chloride bath may contain also chromium or aluminium chloride. After tanning in this way the leather may be treated with precipitating reagents, such as ammonia, alkalis, alkaline salts, phenols, naphthols, organic carboxylic acids, vegetable tannins, soap, sulphides, polysulphides, etc. By alternate treatment with iron salts and ammonia as much as 30% of ferric oxide may be fixed in the leather without destroying its quality.

—J. F. B.

Tanning. J. Y. Johnson, London. From Badische Anilin and Soda Fabrik, Ludwigshafen, Germany. Eng. Pat. 111,141, Nov. 11, 1916. (Appl. No. 16,204 of 1916.)

CRYSTALLINE aromatic compounds containing a sulphonic or carboxylic group or both, soluble in water, and capable of precipitating glue and gelatin from solution, are used for tanning, instead of the amorphous materials hitherto used. Several examples are given. For instance, dihydroxyditolylmethane is treated with sulphuric acid, the sodium salt of the sulphonic acid produced is precipitated with common salt, and the aqueous solution of the sodium salt used for tanning in the ordinary way, after the addition of a little sulphuric acid. (Reference is directed, in pursuance of Sect. 7, Sub-sect. 4, of the Patents and Designs Act, 1907, to Eng. Pats. 22,516 of 1894, 287 of 1908, 8512 of 1912, and 8818 of 1914; this J., 1909, 153; 1913, 205; 1915, 1155.)

—F. C. T.

Adhesive. G. H. Brabrook, Assignor to A. T. Fletcher, Boston, Mass. U.S. Pat. 1,241,463, Oct. 30, 1917. Date of appl. Apr. 1, 1916.

AN adhesive is made by dissolving casein in a solution of a cupran ammonium compound. Lime water may be added.—F. C. T.

Horny bodies; Process and apparatus for making — particularly of clear translucent or transparent quality from mealy albuminous masses as casein. A. Kohner, Berlin. Eng. Pat. 102,375, Nov. 15, 1916. (Appl. No. 16,386 of 1916.)

THE finely-divided material is whirled in a container and moistened by spray or mist from an atomiser, operated by steam or compressed air or both. An addition of 15–20% of water leaves the mass still in the form of meal, and in a suitable condition for moulding under high pressure.

—F. C. T.

Process of treating seeds and nuts for obtaining oil and other products [laurin]. U.S. Pat. 1,244,995, See XII.

XVI.—SOILS; FERTILISERS.

Hygroscopic coefficient [of soil]; Direct determination of the —. F. J. Alway, M. A. Kline, and G. R. McDole. J. Agric. Res., 1917, 11, 117–166. (See also this J., 1917, 10.)

HILGARD'S method was investigated. A moist chamber was prepared consisting of a paraffined wooden box and lid, with a metal tray fitting in the bottom containing a layer of water, and with blotting paper lining the sides and reaching to the bottom of the metal tray. A galvanised wire table was held in position about an inch above the water and an inch from the sides of the box. On this table the tray containing the layer of soil was placed. The box was placed in a dark cellar at a constant temperature of 22°–24° C. in summer and 17°–20° in winter. The soil was

dried at 100°–110° C. before starting the determination; this did not raise the result over that of an air-dried sample. It was found that the amount of hygroscopic moisture increased with an increase in temperature. A time of exposure to the saturated atmosphere of less than 12 hours was insufficient and of more than 24 hours was unnecessary. A soil holding its maximum hygroscopic moisture loses this very rapidly on being brought into the ordinary atmosphere, but if the samples during a determination are removed rapidly, within 30 seconds, from the moist chamber into the drying tubes no error is caused. The most advantageous materials for the soil tray were found to be copper and aluminium, although glass, graniteware, and vulcanised rubber gave satisfactory results; pasteboard gave low results. Not more than two trays should be placed in a box. A soil containing pebbles or gravel should be broken with an iron pestle to pass through a sieve with a 1 mm. mesh. The method was found to give reliable results.—J. H. J.

Nitrate-nitrogen accumulation in soil; Some factors affecting —. P. L. Gainey and L. F. Metzler. J. Agric. Res., 1917, 11, 43–61.

PRELIMINARY experiments were made upon the effect of the variations in the methods of investigation of nitrification in soil upon the results obtained. Ammonium sulphate was used as the source of nitrogen and was added at the rate of 60 mgms. of nitrogen per 100 grms. of soil, which was a silt loam. Calcium carbonate and water were also added, and the soil was kept in a moist chamber for four weeks at the ordinary temperature. Nitric nitrogen was determined by a modified phenoldisulphonic acid method. It was found that the quantity of soil used, the depth of the column of soil, the ratio of surface to volume, and the amount of evaporation had little effect upon nitrification. The compactness of the soil was of importance; if much compressed, nitrification ceased a few inches below the surface. These results indicated that access of air appeared to be the controlling factor, and further experiments were made from this point of view. It was found that as the moisture content of a soil decreased, an increase in its compactness brought about an increase in nitrification. The moisture content varied with the compactness, and was found to be an optimum when it amounted to two-thirds of the amount retainable with the particular degree of compactness. Increase in compactness did not affect aeration to a depth of two feet, provided the moisture did not exceed the optimum. Nitrification took place less rapidly in a pulverised than in an unbroken soil. Even in a soil uncultivated for seven years, aeration was in excess of that necessary to maintain aerobic conditions. The conclusion is drawn that increased aeration is not the cause of the beneficial effect observed to follow cultivation.

—J. H. J.

Basic slags; Yields of grass from [manuring with] various —. A. W. Oldershaw. J. Board Agric., 1917, 24, 819–826.

EXPERIMENTS were made upon the application of basic slag of various degrees of solubility to a heavy boulder clay soil in Suffolk for a period of four years, the results being judged by the yields of green grass obtained. The slag was applied at the rate of 40 lb. of phosphoric acid per acre. A plot without manure gave the lowest yield of grass, and the other plots gave increasing yields in the following order: ground Belgian phosphate, slag of low total phosphate and low solubility, slag of low total phosphate and fairly high solubility, slag of high total phosphate and high solubility, and slag of low total phosphate and high solubility. Applied at the rate of 10 cwt. per acre, a slag of low percentage of total phosphate

and high solubility gave more than double the yield of grass given by a slag of low percentage of total phosphate and low solubility. The conclusion is drawn that the citric acid solubility of the phosphate in a slag is a factor of great importance in determining the response of a soil of the above character to treatment with the slag.

—J. H. J.

Sulphur: Effect of—on different crops and soils. O. M. Shedd. J. Agric. Res., 1917, 11, 91—103. (See also this J., 1916, 749.)

EXPERIMENTS were made to determine whether the application of sulphur to soils low in sulphur content was beneficial to crops grown on them. Eight different types of soil in Kentucky were used and the seeds planted were soy beans, clover, oats, alfalfa, and wheat. The experiments were done in dried jars, 100 lb. and 200 lb. per acre of flowers of sulphur being added to the soil, together with the requisite amounts of calcium phosphate, potassium nitrate, and calcium carbonate. The weights of the crops obtained were determined. The results were very varied. In the majority of cases there was a gain in weight of crop from the use of sulphur, but with some plants on some soils its use was injurious. Where gains occurred, both the total sulphur and the sulphate sulphur were increased proportionately to the amount applied. The gain of sulphur in the case of clover and alfalfa was in the form of sulphate, while with soy beans it was in some other form, and in this case also the protein was frequently increased. Sulphate was formed during germination of the seeds, except in the case of clover.

Ammonium citrate solutions; Preparation of—, and determination of insoluble phosphoric acid [in fertilisers]. P. McG. Shuey. J. Ind. Eng. Chem., 1917, 9, 1045.

A NEUTRAL solution of ammonium citrate can be quickly prepared by mixing commercial citric acid dissolved in water with the calculated quantity of concentrated ammonia; 4 lb. of citric acid is added to 6961 c.c. of water and 1760 c.c. of ammonia (sp. gr. 0.900 at 15° C.) is stirred in; 9512 c.c. of solution (sp. gr. 1.09 at 20° C.) is obtained and this is neutral to corallin. Extreme precautions to secure neutrality of samples of mixed manure before determining the insoluble phosphoric acid are not regarded as essential. Concordant results can be obtained without them.

PATENT.

Soil: Treatment of—for improving its productivity. The Thames Bank (Blackfriars) Iron Co., Ltd., Thornaby-on-Tees, and S. Hopkins and A. D. Greaves, London. Eng. Pat. 111,254, June 20, 1917. (Appl. No. 8843 of 1917.)

CAVITIES in the soil from which roots have been removed are treated for a few minutes with a jet or spray of hot water between 180° and 210° F. (preferably 190° F.), and the whole area of the root cavities then dug over and treated for several hours with hot water between the above-mentioned limits of temperature. The latter process may also be used alone, though it is preferable to use both treatments.—C. A. M.

XVII.—SUGARS; STARCHES; GUMS.

"Norit" (decolorising carbon) process of refining as applied in a beet sugar factory. W. H. Giffard. Intern. Sugar J., 1917, 19, 506—509. (See also this J., 1915, 370.)

EXPERIENCE in a Dutch beet sugar factory has

shown that by remelting the second and third product sugars and treating the resulting liquor with "Norit," a high-grade sugar is obtained. A mixture of 3 hectol. of a suspension of the decolorising carbon (produced by the addition of 80 kilos. to 40 hectol. of cold water) and 40 hectol. of the sugar liquor was stirred in a circular tank for about 20 minutes, and the temperature gradually raised to 90° C. A little phosphoric acid was added to the liquor, which was boiled and allowed to stand for about 12 hours. It was passed first through filter-presses and next through the ordinary filters, and finally run into tanks to await boiling to grain in the vacuum pans. The "Norit" from the filter-presses was regenerated by boiling for one hour with a solution of soda and then washing with water. When after continued use the ash content of the "Norit" had risen from the original 6% to 12%, revivification was effected by boiling with hydrochloric acid, and subsequently washing well with water. Additional fresh decolorising carbon was added from time to time to maintain the necessary quantity. It is stated that when the process is in thorough working order it is sometimes possible to reduce the amount of dry "Norit" used to 1.8% of the weight of sugar under treatment.—J. P. O.

White sugar; Report on experiments investigating Weinrich's dry lime process of making—. J. P. Ogilvie. Intern. Sugar J., 1917, 19, 450—452.

IN experiments recently carried out in the Guanica Centrale, Porto Rico, for the purpose of investigating Weinrich's dry lime process of making white sugar (U.S. Pat. 1,084,772 of 1914; this J., 1914, 212), it was found that after the second carbonatation an almost water-white and perfectly clear juice was obtained, from which a satisfactory white sugar could be recovered by boiling, the press-cakes, moreover, being uniformly hard and of low sugar content. A lime-kiln not being available, gas containing only about 13% CO₂, obtained from an Otto producer charged with coke to which limestone had been added from time to time, was used. No sulphur was employed, but after the second carbonatation the juice was treated with a small quantity of phosphoric acid. Owing to the low carbon dioxide content of the gases, carbonatation was slow, and a certain amount of glucose (dextrose) was destroyed; the average gain in purity was 3.25%. At times, however, when carbonatation could be operated more rapidly and a low temperature could be maintained, the gain in purity was as high as 7%, while the amount of dextrose destroyed was insignificant. Similarly favourable results were obtained with a first molasses of 55° purity. It is claimed that with a fully-equipped plant the average gain in purity would be 5° without the destruction of any appreciable quantity of the dextrose present, thus obtaining by a comparatively economical and simple process results superior to any so far attained with the ordinary double carbonatation process as carried out in Java and elsewhere.—J. P. O.

XVIII.—FERMENTATION INDUSTRIES.

Grape marc; Utilisation of—as fuel. C. Matignon and G. Marchal. Comptes rend., 1917, 165, 718—721.

VERY large quantities of grape marc are at present not utilised. It is not generally employed as feeding stuff or fertiliser, though it contains about the same proportions of nitrogen, phosphorus, and potash as farmyard manure. The average moisture-content of fresh marc is about 65% and this could without difficulty be reduced to 25—30% by air drying under sheds. Marc

from the Chablis district (Yonne), dried at 115° C., had the following composition:—C, 48.2%; H, 5.45%; N, 2.4%; ash, 11.6%, including CaO, 2.64%; K₂O, 2.34%; SiO₂, 2.27%; Al₂O₃ + Fe₂O₃, 1.77%; P₂O₅, 1.08%. From analyses published by Muntz, however, it appears that the average ash-content is nearer 6%. The calorific value of the dried marc, after allowing for the evaporation of the water produced by combustion, was found to be 4400 cal. (7900 B.T.U. per lb.), and the temperature theoretically attainable 1930° C. From these data the authors conclude that grape marc could be utilised as fuel, given suitable plant. The fuel value of the marc produced annually in France is estimated as equivalent to at least 160,000 tons of coal.—J. H. L.

Attempted biochemical synthesis of diglucosides of polyhydric alcohols. β-Diglucoside of glycol. Bourquelot and Bridel. See XX.

PATENTS.

Fermented beverages; Method and apparatus for producing dealcoholised —. G. Ciapetti, Rome, U.S. Pat. 1,243,811, Oct. 23, 1917. Date of appl., May 8, 1912.

THE beverage, previously deprived of the greater part of its ethers and gases, is caused to flow over a succession of heated surfaces in a thin film to drive off a portion of the alcohol with a portion of the water. The alcohol and water thus driven off are separated from one another, the water is cooled and re-introduced into the beverage in separate portions, one immediately after the beverage has passed each heated surface, to maintain the volume substantially constant and to assist in maintaining a low temperature.—J. F. B.

XIXA.—FOODS.

Wheat, rice and maize grains; Distribution of the [antineuritic] substance in —, the deficiency of which in a diet causes polynuritis in birds and beri-beri in man. H. Chick and E. M. Hume. Proc. Roy. Soc., 1917, B, 90, 44–60.

IN the case of wheat and rice grains, the antineuritic vitamin is concentrated mainly in the germ or embryo; it is also present to a less extent in the bran. Ordinary white (wheaten) flour is deficient in the substance and, if used as an exclusive diet, will induce polynuritis in pigeons or beri-beri in man. The embryo of maize grains also possesses marked antineuritic properties. The addition of wheat germ to a diet of polished rice in quantity (3 grms. every second day) sufficient to prevent polynuritis in pigeons, also maintains the weight and general health of the birds; in larger quantities (2 to 3 grms. every day) it leads to great increase in the body-weight. Tinned meats and vegetables are deficient in anti-beri-beri vitamins and a diet consisting of these preserved foods should be supplemented by wheaten bread containing the germ of the grain.

—W. P. S.

Substance (vitamine) whose deficiency in a diet causes polynuritis in birds and beri-beri in man; Effect of exposures to temperatures at or above 100° C. on the —. H. Chick and E. M. Hume. Proc. Roy. Soc., 1917, B, 90, 60–68.

THE antineuritic vitamin present in the embryo of wheat grains is not injuriously affected when the embryo is heated at 100° C. for two hours, but its properties are destroyed rapidly at 120° C. The vitamin contained in yeast extract is also destroyed at 120° C., but not at 100° C.—W. P. S.

Bread-making; Use of lime in —. J. Effront. Monit. Scient., 1917, 61, 241–246.

THE acidity of flour and the bad odour and keeping qualities of bread are not caused by enzymes in the bran but are due to bacterial action, the growth of the bacteria being promoted by defective drying of the grain. The enzymes and bacteria are not affected by small quantities of acids or alkalis, and the use of lime-water in making the dough is useless, if not even injurious, when a poor yeast is employed. Bread made with the use of lime-water is less digestible than ordinary bread owing to the conversion of the acid phosphates into insoluble phosphates.—W. P. S.

Phytin phosphorus in plant products; Determination of —. J. B. Rather. J. Amer. Chem. Soc., 1917, 39, 2506–2515.

THE accuracy of the method proposed by Heubner and Stadler for the titration of phytin with ferric chloride solution (this J., 1914, 713) was confirmed by titration of sodium and strychnine salts of phytin from various plant products. The ratio of iron to phosphorus, 1:1.19, accords with the formation of a hepta-ferric salt of inositol-pentaphosphoric acid and insolar confirms the author's previous conclusions as to the composition of phytin (see this J., 1917, 562). The method may be applied to the determination of phytin phosphorus in plant products, such as seeds, as follows:—8 grms. of the finely-ground material is digested with 200 c.c. of 1.2% hydrochloric acid for 3 hours at the ordinary temperature, with frequent shaking. Fifty c.c. of the filtered extract, in a slender conical beaker of about 150 c.c. capacity, is treated with 10 c.c. of 0.3% ammonium thiocyanate solution and 40 c.c. of water, and titrated with a 0.6% hydrochloric acid solution of ferric chloride containing 0.7344 gm. of iron per litre. In a similar beaker 100 c.c. of 0.6% hydrochloric acid containing the same amount of thiocyanate as the liquid to be titrated, is treated with 0.1–0.2 c.c. of the ferric chloride solution, to serve as colour standard. The titration is complete when the supernatant liquid, above the whitish iron precipitate, viewed by reflected light, shows a reddish coloration equal to that of the standard, and persisting for 5 mins. The volume of ferric chloride solution required is reduced by that added to the standard. One c.c. of the ferric solution corresponds to 2 mgrms. P₂O₅ or 0.8739 mgrm. of phosphorus present as phytin. The end-point is most distinct when the liquid contains not more than 10 mgrms. of phytin phosphorus. Substances other than phytin, present in extracts prepared as above, do not affect the results. The following percentages of phytin phosphorus were found in the products named:—maize, 0.19–0.20; cottonseed meal, 0.76–0.86; wheat shorts, 0.61; kafir, 0.23; wheat bran, 1.24; oats, 0.26; rice bran, 1.18; rice polish, 1.26; soya bean, 0.36; clover seed, 0.29. These amounts ranged from 52 to 89% of the total phosphorus present in the products, and from 74 to 97% of the phosphorus extracted by 1.2% hydrochloric acid. The method does not

appear to give satisfactory results with dried forage plants (soya bean, cow pea, velvet bean, and alfalfa) on account of the dark colour of the extracts.—J. H. L.

Humin formed by the acid hydrolysis of proteins : Origin of the ——. Hydrolysis in presence of formaldehyde. R. A. Gortner and G. E. Holm. Paper No. 81. Journal Series of Minnesota Agric. Expt. Station. J. Amer. Chem. Soc., 1917, 39, 2177–2501.

THE authors first investigated the influence of formaldehyde on the hydrolysis of fibrin and gelatin by prolonged boiling with 20% hydrochloric acid (see Gortner, this J., 1916, 1030). The products were analysed by Van Slyke's methods (this J., 1911, 771; 1915, 1110). With increasing amounts of added formaldehyde (trioxymethylene), the curve representing the amounts of acid-insoluble humin nitrogen formed in the experiments with fibrin, rose sharply to a maximum and then fell again, the acid-soluble humin nitrogen rose somewhat less rapidly to a much higher maximum and then fell, whilst the ammonia fraction first decreased and then increased steadily and rapidly with larger additions of formaldehyde. In the experiments with gelatin, which unlike fibrin contains no cystine, tyrosine, nor tryptophane and only traces of histidine, formaldehyde had no influence on humin formation; the amount of insoluble humin was in all cases extremely small, and that of soluble humin was much smaller than with fibrin. With increasing amounts of formaldehyde the ammonia fraction increased rapidly, as with fibrin, but without any preliminary decrease. Addition of cystine, histidine, and tyrosine, with or without formaldehyde, had no influence on the formation of insoluble humin in gelatin hydrolysis; tyrosine increased the soluble humin, which however was not black but reddish-yellow and therefore not the true humin of protein hydrolysis. Addition of tryptophane, on the other hand, increased the production of insoluble humin even without formaldehyde; and in presence of increasing amounts of the latter the production of insoluble humin increased to a maximum and then decreased as in the case of fibrin. Indole behaved like tryptophane in this respect but pyridine had no influence on humin formation. When the quantity of added formaldehyde was such as to produce the maximum amount of insoluble humin, the nitrogen of the latter corresponded approximately with that of the tryptophane originally present, and half of it was found to be amino-nitrogen. The authors conclude (see this J., 1916, 1030) that the formation of black insoluble humin in protein hydrolysis by acids, is due to interaction between tryptophane and some as yet unidentified aldehyde or ketone, and the only part which any of the other known amino-acids has in humin-formation is perhaps to furnish some of their nitrogen to the humin fraction either through adsorption or occlusion (cp. Roxas, this J., 1916, 1171). The amino-group of tryptophane is not involved in the primary reaction by which insoluble humin is formed; probably it is the α -position of the indole nucleus which is reactive. The initial fall in the so-called ammonia fraction observed in the experiments with fibrin is probably due to the removal in the insoluble humin, of some compound (tryptophane), which, when no aldehyde is present, contributes nitrogen to the ammonia fraction. The rapid rise in the ammonia curve with larger additions of formaldehyde, is due to the de-amination of amino-acids and the formation of volatile alkaline compounds other than ammonia, the nature of which is still under investigation.—J. H. L.

PATENTS.

Cereals, pulses or other grain : Process for treating — for edible purposes. T. W. Rees, and The Eastern Flour Co., Ltd., Staines, Middlesex. Eng. Pat. 110,945, Nov. 9, 1916. (Appl. No. 16,070 of 1916.)

CEREALS, pulses, or other grain are steeped, in their natural state with their skins or husks on, in an alkaline solution, e.g., of sodium bicarbonate in the proportion of about 1 lb. per gallon of water. When a sufficient quantity of liquid has been absorbed, the material is sprayed with or immersed in a suitable acid solution other than sulphurous acid, e.g., sulphuric or tartaric acid at a strength of about 1 oz. per gallon of water. The material is then immediately dried by heat in a revolving drying machine until the moisture has been evaporated and the natural flavour modified. After cooling, the husks will readily leave the kernel, which may be ground to flour or otherwise utilised.—J. F. B.

Food products consisting of globules of starchy material and methods of preparing same. A. E. White, London. From Kellogg Toasted Corn Flake Co., Battle Creek, Mich., U.S.A. Eng. Pat. 111,119, Aug. 10, 1916. (Appl. No. 11,309 of 1916.) (See Eng. Pat. 18,916 of 1913; this J., 1913, 920.)

STARCHY material is mixed with water and sweetening and seasoning substances, with or without the addition of flavouring or colouring matters, to form a moist friable cake. This is granulated into small flaky particles, and these are rolled and shaken in a rotating drum, which is also subjected to a jarring action, until round globules are formed, and these are cooked until sufficiently gelatinised, and then rapidly heated by dry heat until puffed up into a light porous product, which, if desired, may be toasted by the further application of heat.—C. A. M.

Fruit and vegetables : Preservation of —. D. Chambers, Chideock, Dorset. Eng. Pat. 111,112, Nov. 13, 1916. (Appl. No. 16,223 of 1916.)

A room for the preservation of fruit and vegetables is constructed with a raised perforated floor of sheet iron, steel, or tin above a surface of earth which has been dug and dressed with a mixture of lime, salt, sand, and crude pitchblende, "which distributes to the contents of the fruit room mild currents of emanations of magnetism, electricity or radium." The walls of the room are coated with a mixture of lime, salt, cloves, allspice, and size, and wooden or metal rods are provided on which the fruit or vegetables may rest or be suspended. Apples and the like are wired, and enclosed in germ-proof air-tight paper bags, which are enclosed in inverted sterilised jars or boxes. A steam box with a glass near the top is provided for sterilising fruit or jars of fruit, and this contains a kettle, lamp, and trays for holding fruit skewers, etc.—C. A. M.

Cereal pastes : Drying room for —. N. D'Agostino, Assignor to A. Bizzarri and R. Rauli, Los Angeles, Cal. U.S. Pat. 1,244,429, Oct. 23, 1917. Date of appl., Sept. 5, 1916.

THE apparatus consists of a casing divided into compartments communicating with each other, one of them being adapted to contain the material to be dried and having an opening to the outside, capable of being regulated, and the other being closed and containing a blower with a deflector for directing the air currents from the one compartment into the other through the communicating opening.—J. F. B.

Vegetable drying oil [and cattle food]. U.S. Pat. 1,244,521. See XII.

XIXB.—WATER PURIFICATION; SANITATION.

Hardness in water: Note on the Blacher method for the determination of —. A. S. Behrman. Philippine J. Sci., 1916, 11A, 291—293.

VARIOUS points in the Blacher method (this J., 1913, 158) were examined. The presence of as much carbon dioxide as 28 parts per million was not found to interfere with obtaining correct results, and higher amounts were easily reduced by the aspiration of air for 5 mins., which was as efficient as boiling. Amounts of sodium chloride corresponding to 2000 parts of chlorine per million did not affect the end-point. It was found desirable to dilute a water with a total hardness of over 250 parts per million about five times. There are two end-points to the titration in presence of phenolphthalein, the first being a faint pink, the second an intense pink; the latter point gives correct results. The following method of carrying out the test is recommended:—The free carbon dioxide in 100 c.c. of the sample is determined by titration with sodium carbonate in presence of phenolphthalein. If this result exceeds 25 parts per million, the temporary hardness is determined on another quantity of 100 c.c. by aspirating for 10 mins. and titrating with N/10 sulphuric acid, using a drop of dimethylaminoazobenzene as indicator. A few drops of N/10 sulphuric acid are then added in excess, air aspirated through the solution for 5 mins., and 1 c.c. of phenolphthalein (1%) added, followed by N/10 alcoholic caustic potash until a slight pink colour is noticed. Titration is then carried out with N/10 potassium palmitate (made by neutralising an alcoholic glycerin solution of palmitic acid, and then standardising with saturated lime water) until an intense pink is obtained. This result gives the total hardness.—J. H. J.

Water; Identification and determination of zinc in —. R. Meldrum. Chem. News, 1917, 116, 271—272.

Two hundred c.c. of the water is treated with 1 c.c. of concentrated hydrochloric acid, evaporated to 80 c.c., and 1 c.c. of concentrated ammonia is added; the precipitated iron and aluminium hydroxides, if present, are filtered off, dissolved in a small quantity of hydrochloric acid, reprecipitated with ammonia, and again filtered off. The combined filtrates are diluted to 100 c.c. in a graduated cylinder, and 2 c.c. of concentrated ammonium sulphide is added. If, after the lapse of 15 mins., a distinct opalescence or turbidity develops, zinc is present in the water and its quantity may be determined by comparison with the turbidity produced by a known amount of zinc under the same conditions. The method will detect about 1 part of zinc in 100,000 parts of water.—W. P. S.

Dakin or Carrel-Dakin (hypochlorite antiseptic) solution; The —. I. Griffith. Amer. J. Pharm., 1917, 89, 197—500.

The original Dakin solution consisted of hypochlorite in conjunction with boric acid. This preparation, however, was found to have irritating properties when applied to wounds and has been modified by Daufresne by the substitution of sodium bicarbonate for the boric acid. The solution is made from bleaching powder, according to the following recipe, which is calculated on the basis of 30% of available chlorine in the bleaching powder:—151 grms. of bleaching powder is placed in a 12-litre bottle with 5 litres of water, the mixture is shaken vigorously for a few minutes and allowed to stand, with intermittent shaking, for 12 hours. 77 grms. of dry sodium carbonate

and 61 grms. of sodium bicarbonate are dissolved in 5 litres of water and added to the mixture in the bottle. After the calcium carbonate has settled, the solution is siphoned off through a filter and is ready for use. The liquid must contain between 0.15 and 0.50% of sodium hypochlorite and must give no pink coloration when 0.2 gm. of phenolphthalein is sprinkled over its surface. If the available chlorine in the bleaching powder be different from 30%, the above quantities of ingredients must be corrected accordingly.

PATENT.

Insecticidal composition [from smelter fume dust]. W. R. Macklind and E. C. Holton, Assignors to The Sherwin Williams Co., Cleveland, Ohio. U.S. Pat. 1,211,153, Oct. 23, 1917. Date of appl. Oct. 17, 1916.

RECOVERED smelter fume dust containing arsenic is mixed with calcium oxide in amount less than one-half (e.g. 30%) of the arsenic contained in the dust.—J. F. B.

XX.—ORGANIC PRODUCTS; MEDICINAL SUBSTANCES; ESSENTIAL OILS.

Hydrogen cyanide; New plant, Isopyrum fumarioides, yielding —. M. Mirande. Comptes rend., 1917, 165, 717—718.

THE Siberian plant, *Isopyrum fumarioides*, L. (*Ranunculaceae*), is one of the most strongly cyanogenetic known; a 100-grm. sample, representing all parts of the plant, yielded 0.249 gm. of hydrogen cyanide on digestion with water for several hours at 25—30° C. A much smaller amount, 0.012 gm., had previously been obtained from *I. thalictroides*, the only European plant of the same genus.—J. H. L.

Biochemical synthesis of diglucosides of polyhydric alcohols; Attempted —. β -Diglucoside of glycol. E. Bourquelot and M. Bridel. Comptes rend., 1917, 165, 728—730.

EMULSIN was allowed to act for 2 months on an aqueous solution of ethylene glycol (1 mol.) and dextrose (2 mols.). Synthesis of hexobioses occurred (cp. this J., 1915, 161), but the change in rotatory power indicated other reactions as well, the products of which, however, could not be isolated.—J. H. L.

Cyanuric acid; Identity of — with the so-called "tetracarbonimide." E. H. Walters and L. E. Wise. J. Amer. Chem. Soc., 1917, 39, 2172—2177.

SHOREY and Walters (this J., 1915, 239) found in soils a compound having the properties of the "tetracarbonimide" obtained by Scholtz by the oxidation of uric acid by hydrogen peroxide in alkaline solution (Ber., 1901, 34, 1130). The authors have repeated Scholtz's experiments, and find that the "tetracarbonimide" formed is in reality cyanuric acid (cp. this J., 1917, 1057). By modifying the method of oxidation employed by Scholtz, they have isolated another product, probably carbonyldiurea, $\text{CO}(\text{NH}\cdot\text{CO}\cdot\text{NH})_2$, which no doubt is an intermediate product in the oxidation of uric acid to cyanuric acid, for on heating with alkalis, or alone above 227° C., it decomposes into the latter and ammonia.—J. H. L.

Contact catalysis. Studies in decomposition of ethyl alcohol. C. J. Engelder. J. Phys. Chem., 1917, 21, 676—701.

BANCROFT (this J., 1917, 1169) has recently proposed the view that adsorption of the reagents or of the reaction products represents the mechanism

of so-called "contact catalysis." Ethyl alcohol can undergo catalytic decomposition in two different ways, giving rise either to ethylene and water or to aldehyde and hydrogen. Experiments are now described in which alcohol vapour was passed over various catalysts between 380° and 500° C., and the results are compared with those obtained under similar conditions with a mixture of alcohol and water vapours. The catalysts used were aluminium oxide, silica, zirconium oxide, and titanium dioxide; under normal conditions these cause the simultaneous but unequal occurrence of the dehydration and dehydrogenation processes, aluminium oxide, indeed, assisting the former change almost exclusively. In every case, however, the admixture of water vapour with the alcohol causes a relative retardation of the dehydration process and therefore a decrease in the proportion of ethylene and an increase in the proportion of hydrogen in the gaseous products. This result is explained by the partial adsorption of the additional water vapour by the catalyst and a consequent smaller adsorption of water from the alcohol molecules. A similar but reverse effect was observed on submitting a mixture of alcohol vapour and hydrogen to the catalytic influence of titanium oxide, the dehydrogenation process in this case being partially suppressed. Titanium oxide catalyses very slightly the formation of ethane from a mixture of ethylene and hydrogen near 400° C. and does not induce appreciably the decomposition of ethylene into methane nor of aldehyde into carbon monoxide and methane. At 210° C. aluminium oxide converts alcohol into ether, and the formation of ethylene at higher temperatures is due to the further dehydrating action of the alumina on the ether; the production of acetaldehyde in the presence of alumina occurs of course by direct dehydrogenation of the alcohol molecule. Finely-divided nickel is well known to be a very active catalyst for the dehydrogenation of alcohol, but it also tends to induce the further decomposition of acetaldehyde into methane and carbon monoxide. So powerful is nickel as a dehydrogenating catalyst that alcohol when submitted to the influence of a mixture of alumina and nickel at 380° C. undergoes decomposition almost entirely by dehydrogenation into acetaldehyde. The most active form of alumina was obtained by treating aluminium nitrate solution with ammonia and dehydrating the washed and carefully-dried precipitate at 240° C.; the silica was best produced by pouring an aqueous solution of sodium silicate into dilute hydrochloric acid and heating, the resulting jelly being subsequently broken up, washed, dried, and finely powdered; the zirconia was prepared by calcining the nitrate at a low heat, and the titania by dehydration of the precipitated tetrahydroxide at 150° C.—D.F.T.

The Dakin or Currel-Dakin [hypochlorite anti-septic] solution. Griffith. See XIXb.

PATENTS.

Ureas or thioureas of the aromatic [benzene or carbazole] series; Process for producing —. Farbenfabr. vorm. F. Bayer and Co., Leverkusen, Germany. Eng. Pat. 8591, June 10, 1915. Under Int. Conv., June 11, 1914. Addition to Eng. Pat. 9172 of 1911 (this J., 1914, 825).

AMINO-ACIDYL amino sulphonie acids of the benzene or carbazole series are treated with phosgene or thiophosgene or other substance capable of introducing the CO or CS group. The ureas from *m*-aminobenzoyl - *m*-aminobenzoyl - sulphosalicylic acid

and from *bis* [*m*-aminobenzoyl-] aminocarbazoledisulphonie acid are specially claimed. The products possess valuable therapeutic properties.—F. W. A.

Acetaldehyde; Method of producing —. E. F. Scheller, Lorsbach in the Taunus, Germany. U.S. Pats. (A) 1,244,901 and (B) 1,244,902, Oct. 30, 1917. Date of appl., June 26, 1917.

(A) PURIFIED acetylene, freed from phosphorus compounds, is mixed with steam, and the mixture is passed at an elevated temperature over a catalyst consisting of oxides or combinations of oxides. (B) The exhausted catalyst, *e.g.*, molybdic acid, is regenerated and freed from catalytic poisons by treatment at a high temperature with a current of gas containing oxygen, *e.g.*, air.

—F. W. A.

Halogenation of gaseous hydrocarbons of the paraffin series or of aliphatic hydrocarbons and their halogen derivatives. C. W. Bedford, Tallmadge, Assignor to The Goodyear Tire and Rubber Co., Akron, Ohio. U.S. Pat. 1,245,553, Nov. 6, 1917. Date of appl., June 29, 1914.

IN chlorinating gaseous saturated aliphatic hydrocarbons, *e.g.*, methane, the reaction is induced in direct and intimate contact with a cooling agent capable of removing halogen acids, *e.g.*, ice, in order to limit the reaction and remove the lower chlorinated products by condensation.—F. W. A.

Ethers; Process of manufacturing paraffin —. B. S. Lacy, Sewaren, N.J., Assignor to The Roessler and Hasslacher Chemical Co., New York, N.Y. U.S. Pat. 1,245,742, Nov. 6, 1917. Date of appl., July 21, 1914.

A MIXTURE of the vapours of a hydrocarbon chloride (chloro-hydrocarbon) and an inert gas is treated with a basic oxide, *e.g.*, calcium oxide, at a temperature of from 250° to 450° C. In a cyclic process for the manufacture of ethyl ether, a mixture of 1 vol. of chlorine with not less than approximately 3 vols. of ethane is passed at 300°—550° C. through a suitable reaction vessel, the reaction products are cooled, and the hydrochloric acid is separated by means of water; the moisture is removed from the remaining mixture of ethyl chloride and excess of ethane, and the dry gas mixture is passed over calcium oxide at a temperature of approximately 250°—450° C.; the reaction product is cooled, compressed, and cooled whilst compressed, and the liquefied ether separated from the excess of ethane, which may be used again in the process.—F. W. A.

*Production of aminoalkyl esters and alkylaminoalkyl esters of *p*-aminobenzoic acid.* Eng. Pat. 111,328. See III.

Process of producing toluene [and propane from turpentine]. U.S. Pat. 1,244,444. See III.

XXI.—PHOTOGRAPHIC MATERIALS AND PROCESSES.

Photographic plate; Physical characteristics of the elementary grain of a —. M. B. Hodgson. Communication No. 56 from the Eastman Kodak Research Laboratory. Brit. J. Phot., Oct. 19, 1917, 532—534.

THE author has examined the grain of photographic plates before, during, and after development. Silver bromide occurs as more or less regular semi-transparent crystals, the most common form being the tetrahedron; the size varies between 0.2μ and 8.5μ in the plates examined, and the average size ranges from 1μ to 4μ. In some cases the developed grain retains practically the size and shape of the halide grain, but more

generally there is expansion and distortion during development, which does not occur when the film is merely swollen with water. It is suggested that this is due to a strain of the halide grain produced by the drying of the surrounding gelatin, the strain being released when the coherence of the grain is removed by its reduction to metal, or that gelatin is actually present in the body of the halide grain itself and produces disintegration by swelling. Photomicrographs are shown of the various steps of a Hurter and Driffield step-negative developed for a uniform time, and of strips with uniform exposure and varying development; only in the shorter developments of the latter series is a greater concentration of silver grains apparent in the upper layers of the film. Scheffer's phenomenon of the throwing out of a feeler from a grain during development was observed in only one case of a very thin film on a microscope slide; it is explained as due to stream lines in the spreading of the developer through the film. There is evidence of the development of a grain at several nuclei.—B. V. S.

Development of roll-film, film-packs, plates, and papers; High temperature——. J. I. Crabtree. Communication No. 62 from Eastman Kodak Research Laboratory. Brit. J. Phot., Nov. 2, 1917, 555—559.

IN the development, etc., of plates or films under tropical conditions, i.e., where the solutions and washing water may be at a temperature as high as 95° F. (35° C.), the chief difficulty met with, apart from the actual melting of the swollen gelatin film, is reticulation. This is very easily produced with swollen gelatin by a change of temperature or by an osmotic change such as might be produced by transfer from a solution of one concentration to one of another, or by transfer to an acid solution. It is necessary therefore to keep all solutions at about the same temperature and also to avoid abnormal swelling of the gelatin during any part of the process. The latter may be achieved by (1) hardening before development, (2) hardening during development, or (3) temporary hardening during development and a permanent hardening afterwards. (1) The author obtained better results by the use of formalin than with alum or chrome alum, but with old films weak, foggy negatives were produced. (2) The method of Saal and others of using formalin in the developer, either with or without alcohol or acetone, was found to produce fog, and the use of alum or chrome alum in alkaline developers was of course impossible. (3) The author found this method most generally applicable. Addition of alcohol or acetone to the developer in sufficient quantity to reduce the water absorption appreciably was not possible with a celluloid base. The addition of large quantities of certain salts such as sodium sulphate or sulphite, with addition of bromide to reduce fog, is fairly efficient with most developers, but the best developer for the purpose was found to be:—*p*-aminophenol hydrochloride, 7 grms., sodium sulphite, 50 grms., sodium carbonate, 50 grms., and water up to 1000 c.c., which prevents swelling of the gelatin and develops quickly and cleanly. If the temperature does not exceed 75° F. (24° C.) no further hardening is necessary, the usual acid fixing bath being used; up to 85° F. (29° C.) a chrome alum hardening and fixing bath should be used and at higher temperatures a formalin hardening and fixing bath. This method is applicable to both plates and films; much fewer precautions are necessary with papers, the film of which is generally fairly hard, but it is preferable to use extra bromide in development, an acetic acid stop-bath, and a potash alum hardening and fixing bath.—B. V. S.

Sepia tones by direct development. A. Nietz and K. Huse. Communication No. 53 from the Eastman Kodak Research Laboratory. Brit. J. Phot., Sep. 28, 1917, 497—499.

THE development of very fully exposed printing papers with certain strongly restrained developers tends to give coloured images. The authors have succeeded in producing good sepia tones on "Artura" paper by this process. They find the best developer to be chloroquinol, 5 grms., sodium sulphite, 30 grms., sodium carbonate, 16 grms., potassium bromide, 6 grms., potassium metasulphite, 6 grms., and water 1000 c.c. The colour of the image is due to the size of the silver grains and not to any staining process; the size of the grain increases with development, the colour passing from yellow through red and greenish-black to black. For this reason the exact concentration of the reducer in the developer is not of much consequence, but the concentrations of the alkali, the bromide, and the metasulphite, which control the speed of development, must be carefully observed in order to produce the best tone. Under definite conditions the tone is dependent on the time of development, and exposure must be regulated accordingly; it is from 75 to 100 times that required with the usual developers, a slight printing-out image being visible. The gradation of the paper is somewhat steeper, and softer negatives are required. The tone alters on fixing and drying and can only be properly judged on the dry print.—B. V. S.

XXII.—EXPLOSIVES; MATCHES.

PATENT.

Smoke-producing compound. W. Arthur. Philadelphia, Pa. U.S. Pat. 1,244,940, Oct. 30, 1917. Date of appl., Dec. 6, 1916.

CADMIUM or a material containing cadmium is mixed with a solid oxidising agent, such as a nitrate, capable of supporting combustion, or a mixture of oxidising salts, with or without the addition of finely-divided aluminium or other metal burning with a bright light.—C. A. M.

XXIII.—ANALYSIS.

Alkali metals; The perchlorate method for the determination of——. F. A. Gooch and G. R. Blake. Amer. J. Sci., 1917, 44, 381—386.

IF the volume of the washing solution (97% alcohol containing 0.1% of perchloric acid) is kept quite small, the solubility of the precipitated perchlorates is insignificant; it is unnecessary to saturate the solution with the substance to be washed. A single evaporation with a moderate excess of perchloric acid (0.1 c.c. for each 0.1 gm. of salt) is not sufficient to convert considerable quantities (0.3 gm. or more) of alkali chlorides completely into perchlorate; the treatment should be repeated. A double precipitation is required to separate large amounts (0.3 gm.) of insoluble perchlorates from sodium perchlorate. In the case of rubidium, the precipitate should be digested for 15 mins. with the washing solution. It is to be noted that perchloric acid has a distinct solvent action on glass.—W. P. S.

Textile fibres; Use of—— in microscopic qualitative chemical analysis. E. M. Chamot and H. I. Cole. J. Ind. Eng. Chem., 1917, 9, 969—971.

FROM a study of the method devised by Emich (this J., 1901, 1142; 1902, 498) the authors find that litmus silk of the right colour and intensity may be prepared by treating raw silk for 2 hours with 10% sodium hydroxide solution, washing it

free from alkali, and then dyeing in a 20 % solution of commercial litmus or a 10 % solution of purified litmus, acidified with 3 or 4 drops of sulphuric acid (1:4). The solution containing the silk is evaporated to a thick syrup and the silk then removed, washed in running water, neutralised with very dilute sodium hydroxide solution, and again washed thoroughly. By treating the dyed fibres with dilute acetic acid or sodium hydroxide solution and washing them in running water they are tinted red or blue. Applied to a drop of liquid under the microscope a dyed fibre is capable of detecting hydrochloric acid in $N/4500$ solution, acetic acid in $N/100$ solution, and sodium or potassium hydroxide or ammonia in $N/200$ solutions. In like manner silk or viscose fibres may be dyed in a 0.5 % or 2 % solution of Congo red made alkaline with sodium hydroxide, and then pressed between filter papers. The fibres change colour with many organic acids in concentrations of 0.1 to 1 gm. per litre, and with mineral acids in concentrations as low as 0.01 gm. per litre. Hence they cannot be used to differentiate between organic and mineral acids.—C. A. M.

Aluminium; Separation of—*from iron by means of ether.* S. Palkin. J. Ind. Eng. Chem., 1917, 9, 951–953.

THE solution of the chlorides of iron and aluminium is evaporated to dryness on the water bath and the residue dried at about 120°C . for 30 mins., with occasional stirring. It is then moistened with 0.5 to 1 c.c. of alcoholic hydrochloric acid solution (25 to 35 % HCl) and heated on the water-bath, eventually after the addition of 3 to 4 c.c. of absolute alcohol, until all salts have dissolved and have begun to crystallise out again. About 0.5 c.c. of alcoholic hydrochloric acid is added to the viscous solution, the flask warmed, and the mass treated with 30 c.c. of ether (sp. gr. 0.713 to 0.716 at 25°C .), which should precipitate the hydrated aluminium chloride in a granular form. Forty c.c. of ether is then added, and the solution filtered through a Gooch crucible, the contents of the flask being meanwhile washed with a mixture of 100 parts of ether with 2 parts of alcoholic hydrochloric acid to prevent ferric chloride drying on the white precipitate. The aluminium chloride precipitate is dissolved in water, the solution diluted to about 100 c.c., and, after the addition of about 5 grms. of ammonium nitrate, rendered just alkaline with ammonia (methyl red as indicator), and the precipitate separated, washed, and ignited in a covered crucible. The ethereal solution of iron is distilled, and the residue transferred by means of as little water as possible, together with some hydrochloric acid, to a weighed platinum dish, in which the liquid is evaporated to dryness. The residue of ferric chloride is converted into sulphate and finally to oxide.—C. A. M.

Laboratory methods for benzol-recovery plant operation. Sperr, jun. See IIA.

Method of staining to distinguish between bleached and unbleached sulphite pulps. Bright. See V.

PATENTS.

Anemometers. South Metropolitan Gas Co., E. V. Evans, and J. S. G. Thomas, London. Eng. Pat. 111,015, Feb. 17, 1917. (Appl. No. 2333 of 1917.)

In anemometers where the rate of flow of a current of gas is estimated by the cooling effect on an electrically heated wire, interference by decomposition of the gas by the hot wire or by the action of the gases on the wire, or by a deposit of soot or carbon on the wire, is obviated by coating or encasing the wire in an electrical non-conductor such as glass. The wire may be maintained below a red heat. By using two such wires, one immediately behind the other and, by suitable indicators, observing the difference of the temperature changes, the direction of the current of gas can be ascertained.—B. V. S.

Viscometer. C. Browning, jun., Sacramento, Cal. U.S. Pat. 1,244,025, Oct. 23, 1917. Date of appl., Aug. 16, 1913.

THE apparatus consists of a transparent tube pivoted on a standard and adapted to receive and discharge the liquid under examination. The tube may be jacketed. A sphere of greater specific gravity than the liquid and of smaller diameter than the bore of the tube, is placed in the tube, and means are provided for fixing the tube at any desired angle.—J. H. P.

Apparatus for and process of estimating the volume of acid required to coagulate a given volume of india-rubber latex. Eng. Pat. 100,591. See XIV.

Patent List.

The dates given in this list are, in the case of Applications for Patents, those of application, and in the case of Complete Specifications accepted, those of the Official Journals in which the acceptance is announced. Complete Specifications thus advertised as accepted are open to inspection at the Patent Office immediately, and to opposition within two months of the date given.

1.—GENERAL: PLANT; MACHINERY.

APPLICATIONS.

Arter, Grinding, etc., machines. 19,332, 19,333, 19,334. Dec. 31.

Baker and Prescott. Apparatus for subjecting articles to varying temperatures. 19,041. Dec. 22.

Bullock, and Fraser and Chalmers. Separating machines. 19,235. Dec. 29.

Cracknell, and Ransomes and Rapier. Refrigerating-apparatus. 18,875. Dec. 19.

Davis and Twigg. Gas-fired furnaces. 19,189 and 19,190. Dec. 28.

Laurie. Drying solid substances precipitated from solution in water, etc. 19,209. Dec. 29.

Menzies. Apparatus for treating liquids with gases. 18,870. Dec. 19.

Ross. Grinding-machines. 18,999. Dec. 22.

Wade (Davis). Refrigerating-machines. 19,348. Dec. 31.

COMPLETE SPECIFICATIONS ACCEPTED.

14,531 (1916). Barbet et Fils et Cie. See under XX.

15,477 (1916). Bostaph, and Bostaph Engineering Co. Retort. (111,871.) Dec. 28.

3689 (1917). Richardson and Hammond.

Combined condenser and heat interchanger. (111,961.) Dec. 28.

12,735 (1917). Fairweather (Pacific Evaporator Co.). Drying apparatus. (111,994.) Dec. 28.

II.—FUEL; GAS; MINERAL OILS AND WAXES; DESTRUCTIVE DISTILLATION; HEATING; LIGHTING.

APPLICATIONS.

Boorne. Wet-carbonising. 19,019. Dec. 22.

Comp. pour la Fabr. des Compteurs et Matériel d'Usines à Gaz. Water-gas producers. 18,757. Dec. 17. (Fr., Dec. 19, 1916.)

Drake, and Drakes, Ltd. Vertical retorts for manufacture of gas. 18,996. Dec. 22.

Grocott. Furnaces for generating producer-gas. 18,815. Dec. 19.

Harger. 19,052. *See under XXIII.*

Nelson. Low-temperature distillation of coal, shale, etc. 18,983. Dec. 21.

Pleasance. 18,744. *See under X.*

Schnuck, and Superior Oil and Process Co. 19,305. *See under XII.*

Thaberg. Producing gas from moist fuel in furnaces, gas-producers, etc. 18,911. Dec. 20. (Sweden, June 1, 1915.)

Thompson. 19,065. *See under XI.*

Twynnam. Production of artificial fuel and utilisation of peat. 19,245. Dec. 31.

Walster and Walster. Generating coal gas in retorts. 18,770. Dec. 18.

Williams and Williams. 19,168. *See under XXIII.*

COMPLETE SPECIFICATIONS ACCEPTED.

12,579 (1916). O'Brien. Production of liquid fuel suitable for use in internal-combustion engines. (111,864.) Dec. 28.

15,477 (1916). Bostaph, and Bostaph Engineering Co. *See under I.*

17,698 (1916). Wellington and Etherton. Treatment of refuse liquors from coke ovens and gas works. (111,883.) Dec. 28.

251 (1917). Heyl. Liquid hydrocarbons. (111,933.) Dec. 28.

252 (1917). Heyl. Production of carburetted water-gas. (111,934.) Dec. 28.

3196 (1917). Hammond and Richardson. *See under III.*

3963 (1917). Wollaston. Gas-producers. (111,964.) Dec. 28.

III.—TAR AND TAR PRODUCTS.

COMPLETE SPECIFICATIONS ACCEPTED.

883 (1917). Aylsworth, and Savings Investment and Trust Co. Production of phenol. (103,664.) Dec. 28.

3196 (1917). Hammond and Richardson. Apparatus for distillation and dehydration of coal tar, mineral or vegetable oils, and the like, and debenzolising of wash and other oils and liquids. (111,956.) Dec. 28.

IV.—COLOURING MATTERS AND DYES.

COMPLETE SPECIFICATION ACCEPTED.

17,982 (1916). Sokal (Kalle und Co.) Production of vat dyestuffs. (111,991.) Dec. 28.

V.—FIBRES; TEXTILES; CELLULOSE; PAPER.

APPLICATIONS.

Brown and Cowan. Apparatus for treating paper pulp, etc. 18,952. Dec. 21.

Dubourg. 18,662. *See under XVIII.*

Heys. Beating-machines for making paper-pulp. 18,997. Dec. 22.

Johnston and Sutherland. Treatment of stalk fibres for removal of gum or mucilage. 19,208. Dec. 29.

Russell and Wood. Paper-making machines. 18,938. Dec. 21.

Stevenson. Acetylcellulose. 19,049. Dec. 21.

COMPLETE SPECIFICATIONS ACCEPTED.

3249 (1917). Korselt. Increasing the strength and elasticity and preventing or decreasing the subsequent weakening of non-loaded raw or boiled fibres in silk. (101,681.) Dec. 28.

10,676 (1917). Gadsden. Method of water-proofing and rendering impervious to dust, bags and sacks. (109,252.) Dec. 28.

VI.—BLEACHING; DYEING; PRINTING; FINISHING.

APPLICATIONS.

Jackson. Cloth dyeing, bleaching, etc., machines. 18,933. Dec. 21.

Nevill. Manufacture of printing, etc., surfaces used in calico or wall-paper printing and drying machines. 19,251. Dec. 31.

COMPLETE SPECIFICATION ACCEPTED.

6302 (1917). Tidswell. Machines for printing piece goods. (111,970.) Dec. 28.

VII.—ACIDS; ALKALIS; SALTS; NON-METALLIC ELEMENTS.

APPLICATIONS.

Dreyfus. 19,353 and 19,351. *See under XX.*

Maxted. Synthesis of ammonia. 18,931. Dec. 21.

Nicholson. Utilisation of complex solutions of sodium and ferrous salts. 19,061. Dec. 21.

Toniolo. Manufacture of nitric acid. 19,139. Dec. 27.

COMPLETE SPECIFICATION ACCEPTED.

16,555 (1916). Grossmann. Utilisation of nitro cake. (111,875.) Dec. 28.

VIII.—GLASS; CERAMICS.

APPLICATION.

Danner. Forming sheet glass. 19,311. Dec. 31.

COMPLETE SPECIFICATION ACCEPTED.

17,791 (1916). Cox. Method of gathering glass. (111,890.) Dec. 28.

IX.—BUILDING MATERIALS.

APPLICATION.

Andrews and Evans. Substitute for wood. 19,058. Dec. 28.

X.—METALS; METALLURGY, INCLUDING ELECTRO-METALLURGY.

APPLICATIONS.

Armstrong, Whitworth, & Co., Rowden, and Trevelyan. Production of steel from scrap. 19,229. Dec. 29.

Armstrong, Whitworth, & Co., Rowden, and Trevelyan. Production of steel. 19,221. Dec. 29.

Auld and Tennick. Casting metals. 18,986. Dec. 21.

Basset. Treatment of ores in blast furnaces. 18,974. Dec. 21. (Fr., Dec. 22, 1916.)

De Ducezele et Cie. Formation of adherent metal deposits on common metals. 18,756. Dec. 17. (Belgium, July 30.)

Leech and Slater. Electrolytic preparation of metals and alloys in the form of paste, sludge, or sponge. 19,170. Dec. 28.

Lumsden. Casting ingots. 18,743. Dec. 17.
Marks (U.S. Alloys Corporation). Treatment of iron and steel. 19,313. Dec. 31.

Marks (U.S. Alloys Corporation). Alloy of iron, titanium, and silicon, and process for the production thereof. 19,314. Dec. 31.

Mead and Wood. Metallurgical heating-furnaces. 18,719. Dec. 17.

Parkinson Stove Co., and Thompson. Protection of iron and steel surfaces. 19,057. Dec. 24.

Pleasance. Apparatus for screening and washing gold, sand, coal, etc. 18,744. Dec. 17.

COMPLETE SPECIFICATIONS ACCEPTED.

18,248 (1916). Armstrong, Whitworth. & Co., and Rowden. Manufacture of steel. (111,916.) Dec. 28.

18,329 (1916). Iyer. Coating iron with brass. (112,045.) Dec. 31.

6111 (1917). Cusquel and Goupil. Devices for pulverising molten or liquid metals. (112,085.) Dec. 31.

XI.—ELECTRO-CHEMISTRY.

APPLICATIONS.

Chance and Hunt, Cunningham, Mott, and Smith. Electrolytic processes. 18,900. Dec. 20.

Chem. Fabr. Weissenstein, and Walter. Diaphragms for electrolytic cells. 19,082. Dec. 24. (Austria, Dec. 19, 1916.)

Coates, and Watford Electric and Manufacturing Co. Electric arc furnaces. 18,876. Dec. 19.

Leech and Slater. 19,170. *See under X.*

Thompson. Manufacture of carbon electrodes. 19,065. Dec. 24.

XII.—FATS; OILS; WAXES.

APPLICATIONS.

Bendixen. Methods for keeping fat-globules in emulsions apart. 19,094. Dec. 27.

Buchner. Washing and cleansing agents. 18,966 and 19,039. Dec. 21 and 22.

Davidson. Machines for forming oil cakes. 19,323. Dec. 31.

Schuck, and Superior Oil and Process Co. Process of purifying oily material. 19,305. Dec. 31.

COMPLETE SPECIFICATION ACCEPTED.

3196 (1917). Hammond and Richardson. *See under III.*

XIII.—PAINTS; PIGMENTS; VARNISHES; RESINS.

APPLICATION.

Craven, and Yorkshire Dyeware and Chemical Co. Linoleum manufacture. 18,891. Dec. 20.

XIV.—INDIA-RUBBER; GUTTA-PERCHA.

APPLICATION.

François. Method of impregnating and covering tissues with balata without the use of solvents. 19,224. Dec. 20.

COMPLETE SPECIFICATIONS ACCEPTED.

17,991 (1916). Ransford (Icken). Manufacture of rubber and other products from latexes and treatment of raw, inferior, or scrap rubbers or rubber gums. (111,906.) Dec. 28.

17,992 (1916). Ransford (Icken). Process for purifying raw, inferior, or scrap rubbers. (111,907.) Dec. 28.

XV.—LEATHER; BONE; HORN; GLUE.

APPLICATION.

Aktionernoje Obszestwo Kaoutshouk, and Zirg. Manufacture of a substitute for leather, etc. 18,801. Dec. 18.

XVI.—SOILS; FERTILISERS.

APPLICATION.

Robinson. Manufacture of fertilisers. 18,802. Dec. 18.

XVII.—SUGARS; STARCHES; GUMS.

APPLICATIONS.

Feldenheimer and Plowman. Starch substitutes. 18,749. Dec. 17.

Harris. Starch and farina settling-vats. 18,956. Dec. 21.

XVIII.—FERMENTATION INDUSTRIES.

APPLICATIONS.

Barbet et Fils et Cie. Apparatus for treatment of phlegms or wines or fermented musts. 19,236. Dec. 31.

Dubourg. Manufacture of alcohol from wood or any cellulosic substance. 18,862. Dec. 19. (Fr., Oct. 21, 1916.)

XIX.—FOODS; WATER PURIFICATION; SANITATION.

APPLICATIONS.

Fellowes and Hyatt. Insecticides. 19,008. Dec. 22.

Krogh. Production of colourless soluble albumen of blood. 18,790. Dec. 18.

Malcolm. Treatment of fruit and vegetable refuse. 18,831. Dec. 19.

Pearson. Production of protein substances. 18,866. Dec. 19.

COMPLETE SPECIFICATION ACCEPTED.

8394 (1917). Alcock. Apparatus for treating by heat coffee, cereals, and like materials. (112,100.) Dec. 31.

XX.—ORGANIC PRODUCTS; MEDICINAL SUBSTANCES; ESSENTIAL OILS.

APPLICATIONS.

Coley and Wilbraham. Manufacture of bismuth tribromphenylate. 19,017. Dec. 22.

Dreyfus. Manufacture of acetic acid from acetaldehyde. 19,353 and 19,354. Dec. 31. (Fr., Feb. 22.)

COMPLETE SPECIFICATION ACCEPTED.

14,531 (1916). Barbet et Fils et Cie. Apparatus for recovering ether and alcohol vapours contained in the air of factories. (101,875.) Dec. 28.

XXI.—PHOTOGRAPHIC MATERIALS AND PROCESSES.

COMPLETE SPECIFICATIONS ACCEPTED.

18,104 (1916). Edwards. Photographic films. (111,913.) Dec. 28.

18,631 (1916). Petrelius. Manufacture of colour prints. (103,120.) Dec. 28.

XXII.—EXPLOSIVES; MATCHES.

APPLICATION.

Adde. Explosives. 18,906. Dec. 20. (Ger., Dec. 20, 1916.)

XXIII.—ANALYSIS.

APPLICATIONS.

Harger. Gas calorimeters. 19,052. Dec. 24.
Williams and Williams. Appliance for giving warning of the presence of combustible gases or vapour in the atmosphere. 19,168. Dec. 28.

Fire protection in industrial plants. C. W. Johnson.
J. Amer. Inst. Metals, 1917, 14, 139—147.

THE general principles laid down for fire protection in industrial plants are: (1) everything possible must be done to prevent the start of a fire; (2) positive arrangements so that the start of a fire may be known at once and announced; (3) the provision of trained men with proper equipment and means for bringing them on the scene without loss of time, whatever the period when the fire may start. Rules for the prevention of fires are summarised. The following are dealt with: water supply, sprinklers, hydrants, records, hose, hose carts, chemical engines, hand portable fire extinguishers, hose house and boxes, fire alarm systems, fire pumps, fire escapes, aisles, inflammable materials, refuse materials. Weekly inspections should be arranged to ensure that inflammable and refuse materials, such as petroleum spirit, alcohol, soldering flux, varnish, shellac, linseed oil, waste, wiping rags, etc., are kept in minimum quantities only throughout the works and then only in safety cans or receptacles with covers. All corners, storerooms, etc., in out-of-the-way places should be inspected daily for cleanliness and to ensure that where inflammable materials are stored, every precaution has been taken to prevent fire; for example, canvas-duck treated with linseed oil should be stacked so that there is ample ventilation all around and through the piles, air spaces being provided at 1-inch intervals throughout the height of the pile. All heating pipes should be cleaned outside from dust at least monthly. All motors should be blown out at least monthly. Shields of paper or other inflammable material should not be allowed on incandescence lamps. All wiring should be removed as it becomes obsolete.—B. N.

Filter: Automatic self-cleaning——. O. Best.
San Francisco, Cal. U.S. Pat. 1,246,850, Nov. 20, 1917. Date of appl., Apr. 24, 1916.

LIQUID is forced under pressure into the top of a filtering chamber and passes through a filtering medium at the bottom into a storage chamber below; the two chambers communicate by a vertical pipe having its upper end in the bottom of the filtering chamber below the filtering medium and its lower end near the bottom of the storage chamber. Air is thereby compressed in the storage chamber to a pressure normally less than that in the filtering chamber, and an outlet from the filtering chamber may be controlled so as to reduce the pressure in this chamber and thus cause liquid to flow back from the storage chamber to clean the filter.—W. F. F.

Refrigeration: Process of——. A. W. Browne, Ithaca, N.Y., and R. P. Nichols, Philadelphia, Pa. U.S. Pat. 1,246,866, Nov. 20, 1917. Date of appl., Dec. 3, 1912.

ANHYDROUS ammoniated copper sulphate is heated to a temperature and at a pressure at which ammonia is given off, but below the fusion or decomposition point of the sulphate. The ammonia is condensed to a substantially anhydrous liquid, which is passed through refrigerating passages, and the gaseous ammonia then drawn off at reduced pressure and passed over the residual anhydrous copper sulphate. The original compound is thus re-formed, and the cycle of operations is repeated.—W. F. F.

Evaporator. P. B. Sadler, Chicago, Ill. U.S. Pat. 1,246,939, Nov. 20, 1917. Date of appl., Nov. 10, 1914.

THE liquid to be evaporated is forced by a pump into the conical lower end of a steam drum containing vertical heating tubes for the liquid. The liquid passes from the top of the steam drum down through the annular space formed by the outer casing, which has a conical lower end terminating in an outlet pipe leading back to the pump. A valved outlet is provided between the pressure side of the pump and the inlet chamber of the drum, and a valved by-pass from the inlet chamber around the valve in the outlet pipe.

—W. F. F.

Centrifugal separator. D. B. Weston, Sharon, Mass. U.S. Pat. 1,247,473, Nov. 20, 1917. Date of appl., Nov. 28, 1913.

THE top and bottom members, A¹, A², of a rotating container, A, are provided with large central openings, to permit access to the interior and

discharge of the solid material through the bottom. Liquid to be treated is fed by the pipe, E, into the top of the separator, and an annular baffle-plate, F, is provided having its edges overlapping the discharge outlet, G, for the lighter separated liquid. A discharge outlet, H, is provided for the heavier separated liquid, having its inlet end above the baffle-plate, F, and at a greater radial distance from the centre than the outlet, G. The container is surrounded by a casing having a lower central opening of the same diameter as the opening in the container, A, and is provided with an annular partition, P, forming separate annular collecting troughs for the separated liquids.—W. F. F.

Binding and cohering composition. R. F. Tompkins, New York. U.S. Pat. 1,247,595, Nov. 20, 1917. Date of appl., Feb. 11, 1916.

A BINDING composition is composed of a mixture of a carbonaceous extract of tan bark liquor containing a hygroscopic glucoside, sodium silicate, and water.—W. F. F.

Separating from a stream of liquid, solids held in suspension; Apparatus for——. A. Ross, London. Eng. Pat. 111,509, Nov. 24, 1916. (Appl. No. 16,884 of 1916.)

IIA.—FUEL; GAS; MINERAL OILS AND WAXES.

Carbonising coal. J. West. Gas J., 1917, 140, 563 and 611. (See this J., 1917, 1265.)

EXPERIMENTS on the heating and lighting power of coal gas have shown that probably a gas ranging from about 450 to 500 B.Th.U. would be suitable for all purposes, and the author gives results of tests aiming at the manufacture of gas of this quality. Comparative tests were made in Glover-West continuous vertical retorts under three conditions:—(1) High temperature, without steaming; (2) high temperature, together with steam at 25 lb. pressure; (3) high temperature, with steam at 40 lb. pressure. With Orrell nuts the results were respectively:—Gas made per ton (corrected), 14,989, 17,759, and 21,684 cub. ft.; dehydrated tar per ton, 17.4, 18.2, and 18.6 galls.; ammoniacal liquor (10° oz.), 39.7, 42.4, and 40.3 galls.; gross calorific value, 503, 460, and 142 B.Th.U. The corresponding figures with Wigan Arley Mine coals were:—Gas per ton, 11,507, 15,987, and 23,016 cub. ft.; tar per ton, 16.5, 17.7, and 18.8 galls.; ammoniacal liquor per ton, 29.2, 33.0, and 44.3 galls.; calorific value, 526, 511, and 153 B.Th.U. Summarising these results the author gives the following figures as representing the respective increase in volume of gas per ton of coal as due to:—(1) higher temperature only, (2) higher temperature and 25 lb. steam pressure, (3) higher temperature and 40 lb. steam pressure. Orrell nut coal, (1) 2599, (2) 5369, (3) 9294 cub. ft. Wigan Arley Mine coal, (1) 1673, (2) 3173, (3) 10,182 cub. ft.—J. E. C.

Petrol and other volatile substances; Fractionating apparatus for —. E. Hildt. Comptes rend., 1917, 165, 790—793.

THE apparatus consists of six flasks having wide necks and each provided with a small reflux condenser connected with a side tube at the top of the neck. Each neck is closed by a stopper through which passes a tube closed at the bottom and extending into the neck; suitable tubes connect these tubes in series. The flasks contain petroleum fractions having the following b. pts. respectively:—above 150°, 130°—150°, 110°—130°, 90°—110°, 70°—90°, 50°—70°, and below 50° C. The flasks are heated by separate burners so that the tubes in the necks are surrounded by vapours at the temperatures mentioned. The petrol under examination is admitted, drop by drop, into the first tube and the more volatile portion is at once driven over into the second and succeeding tubes, so that fractions of decreasing b. pts. collect in the series of tubes. Means are provided for drawing off these fractions and for condensing the very volatile vapours which escape from the last tube of the series.—W. P. S.

Benzol recovery plant operation; Laboratory methods for —. II. Method for boiling point test of benzols. P. W. Sperr, jun. Met. and Chem. Eng., 1917, 17, 586—588. (See this J., 1918, 2 A.)

A STANDARD Engler flask is used, of globular shape, 6.5 cm. in diameter, with a cylindrical neck 1.6 cm. in internal diameter and 15 cm. in length. Half-way up the neck a tube of not less than 5 mm. diameter and 10—12 cm. long extends downwards at an angle of 75°. The condenser tube is a straight piece of glass tubing 24 in. long and of $\frac{1}{8}$ in. internal diameter. The outer jacket is 15 in. in length. A standard Bunsen burner, with an opening $\frac{5}{16}$ in. at the top, is used for heating, the flame burning blue at the top. The flask rests on an asbestos slab, $\frac{1}{8}$ in. thick, 6 in. square and having a circular hole 1 in. in diameter in the centre. The furnace, or enclosure for the burner, is cylindrical in shape, 5 in. in diameter and 8 in. high, with four holes 1 in. in diameter located $\frac{1}{2}$ in. below the top. The receiver is a 100 c.c. cylinder graduated in 1 c.c. The thermometer for crude oils and solvent naphthas is graduated in degrees from 0° to 400° C.; for pure benzene and toluene it is graduated in $\frac{1}{100}^{\circ}$ from 70° to 120° C. For the test, 100 c.c. (at 15.5° C.) is measured into the flask and distilled at the rate of 4—5 c.c. per min. For refined products, the following temperature readings are taken: First drop, 5%, 10%, and each 10% to the dry point. For light oils, the temperature of the first drop is read, and the % distillate at the following temperatures:—80°, 95°, 100°, 120°, 150°, 180°, and 200° C. For boiling point tests of refined products, corrections should be made for emergent stem of thermometer and barometric pressure. The above details of the method adopted by the author are based on the European method (Lunge's "Coal Tar and Ammonia," 4th Amer. Edn., p. 755), the American method (Church, J. Ind. Eng. Chem., 1911, p. 227), and the method given in the Gas Chemists Handbook, p. 180, published by the American Gas Institute.—L. A. C.

IV.—COLOURING MATTERS AND DYES.

Logwood; Examination of—Colour Trade Journal, Oct., 1917. J. Amer. Leather Chem. Assoc., 1917, 12, 586–598.

EVIDENCE of the probable value of logwood is obtained by examination of a freshly cut surface, which should be reddish and not grey. The value of the extract depends upon the content of hamatoxylin, formed by fermentation of the glucoside, and hamatein, formed by further fermentation, a process which would eventually destroy the tinctorial power. Colorimetric processes are described depending on the development of colour with alum or with copper salts. The normal ash of logwood contains alkali chlorides and phosphates; the wood should contain less than 2%, the extract less than 3% of ash. The sugar content is determined after removal of hamatoxylin and hamatein by means of hide powder. Pure dry logwood extract contains 87% of ether-soluble and 13% of alcohol-soluble material, whereas the common adulterant, chestnut extract, is almost insoluble in ether but readily soluble in alcohol. A method for determining gelatin, molasses, and chestnut extract is detailed, and the methods to be used for valuing logwood extracts by dye-trials, more particularly in reference to the variable contents of hamatoxylin and hamatein, are discussed.—F. W. A.

V.—FIBRES; TEXTILES; CELLULOSE; PAPER.

Textile plants; The Carbone method for retting—by microbiological action. D. Carbone and A. Tombolato. Annali d'Igiene sperim., 1916, 26, [1]; Staz. sperim. Agrar. Ital., 1917, 4, 261–299, and Progressi Nelle Ind. Tintorie e Tessili, 1917. Bull. Agric. Intell., 1917, 8, 1417–1418.

REFERENCE is made to Rossi's method (this J., 1917, 79) for the retting of hemp, etc., by cultures of a specific pectic ferment, *B. Cornesi*, which in the author's view is identical with or very similar to *B. asterosporus*. This method has given satisfactory results in Italy and France, since it shortens the time of retting, gives no bad smell, and allows inferior hemp to be retted more rapidly than in field retting pools. On the other hand, the product differs from that obtained by field retting; the green parts of the bark remain adherent to the fibres and special machines must be used for separating them and washing the fibre. The resulting material is of a different character from that of the standard product and some temporary difficulty may be experienced in disposing of the fibre to advantage. These differences are attributed to the use in Rossi's process of an aerobic bacillus, which is not a natural agent of the field retting process, having first been isolated from a decomposing potato. In Carbone's process, on the other hand, an obligatory anaerobic bacillus is employed, which was isolated from the mud of retting pits at Bologna and which has been named *B. felsineus*. This bacillus has been found fairly generally distributed in the hemp pits of Italy and is very probably the specific natural retting agent. Together with *Saccharomyces*, this bacillus actively rets hemp, in stalks or green "harl," in less than 2½ days at 37° C. It gives the same type of retting as the field retting, i.e.,

complete detachment of the woody parts and spontaneous exfoliation. This renders the use of special machines and washing unnecessary and the manipulation is the same as in field retting. The Carbone method is being tested extensively on the 1917 crop; in applying it, pools are built, the water is heated to 37° C. by steam or otherwise, and the selected culture is used. Besides hemp, *B. felsineus* is capable of retting other bast fibres and various species of *Malvaceæ* and agave.—J. F. B.

Sulphuric acid and oleum; Thermal properties of—A. W. Porter. Faraday Soc., Dec. 12, 1917. [Advance proof.] 26 pages.

THE thermal properties of sulphuric acid and oleum of different concentrations have been calculated from published data. (1) *Sulphuric acid*. (a) *Heat of dilution at ordinary temperature*. From the data of Pfaundler, Brönsted, and Knietsch (Ber., Oct. 19, 1901; this J., 1903, 172, 313) for the heat of dilution of sulphuric acid, and of Thomsen (*Thermochem. Untersuch.*, 3, 31) for the heat of formation of sulphuric acid from sulphur trioxide and water, the following equation is derived:—

$$D_{15} = \frac{101.5}{[M + 0.2013]^2}$$

in which D_{15} is the true or differential heat of dilution, i.e., the heat set free at 15° C. when a large amount of solution containing 1 gm. of sulphur trioxide and M grms. of water is diluted with 1 gm. of water. (b) *Variation of heat of dilution with temperature*. Using Henning's values for the latent heat of water,

$$D_t = \frac{101.5}{[M + 0.2013]^2} + \frac{0.0413(t - 15^2)}{[M + 0.062]^2}$$

in which D_t is the heat of dilution at temperature t . (c) *Heat of concentration as in Gaillard towers*.

The heat required to evaporate dilute acid containing 1 grm. of sulphur trioxide and M_1 grms. of water until it only contains M_2 grms. of water is

$$L_w(M_1 - M_2) + [h] \frac{M_1}{M_2},$$

in which L_w is the latent heat of evaporation of water and h the heat of dilution of 1 grm. of SO_3 with M grms. of water. The value of this expression when $M_2=0$ is called the *heat of total evaporation*. The utility of this quantity is not impaired by the fact that total evaporation could not take place. If this quantity is plotted for different strengths, it is only necessary to take the difference of the numbers corresponding to the two strengths at the beginning and end of the process, each at the temperature of the evaporation, to obtain the heat of concentration desired. When change of temperature occurs at the same time, a correction is made for the thermal capacity of the solution, and the external work done during evaporation also influences the quantity of heat required. (2) *Oleum*. (a) *Latent heat of evaporation of liquid sulphur trioxide*. This is derived from Knietzsch's values for the vapour pressure of 100% oleum, and is given by

$$L_s = \frac{116.6}{P^{5.0}}, \text{ where } P \text{ is the vapour pressure. (b)}$$

Latent heat of fusion of sulphur trioxide is calculated from Knietzsch's heat of solution for solid and liquid sulphur trioxide. The author disagrees with Knietzsch's smoothed values, and substitutes his own. There is no evidence of the existence of $\text{H}_2\text{S}_2\text{O}_7$. (c) *Heat of solution*. Some corrected values of k_t are tabulated (k_t =heat set free when 1 grm. of water is mixed with m grms. of sulphur trioxide at temperature t). (d) *The heat of evaporation (or condensation) of sulphur trioxide*

vapour is given by $L_s(m_2 - m_1) + [k] \frac{m_2}{m_1}$, where

L_s =latent heat of evaporation of liquid sulphur trioxide, and m_1, m_2 are the initial and final amounts of sulphur trioxide per 1 grm. of water. The *heat of total evaporation of sulphur trioxide vapour* (analogous to the expression found above for sulphuric acid concentration) is tabulated for selected values of m_1 ($m_2=0$). (e) The heat k evolved when 1 grm. of water is mixed with m grms. of liquid SO_3 is given by the equation

$$k = \frac{50.43 m}{1 + 0.2013 m} + \frac{0.714 m (t - 15)}{1 + 0.062 m}.$$

A series of tables is given containing values calculated from the equations derived in the paper, and instructions are given for the construction and reading of an alignment chart, giving results graphically. Several examples are given of the application of the formulae to problems arising in the concentration of sulphuric acid and the manufacture of oleum.—F. SP.

Soda Liquors; Causticising—M. L. Griffin, W. H. Howell, jun., and G. K. Spence. Report of Soda Pulp Committee, Joint Convention of Techn. Assoc. of Pulp and Paper Ind., and Tech. Sect. of Canadian Pulp and Paper Assoc., Sept. 27, 1917. Met. and Chem. Eng., 1917, 17, 599—663.

The report deals with four processes for causticising sodium carbonate liquors and separating the sludge. (1) Intermittent precipitation, sedimentation, and decantation. The alkali, after causticising with lime, is run into a series of tanks in which the sludge is allowed to settle and the clear liquor is decanted. The sludge is washed by dilution and further decantation, the weaker wash liquors being used for washing strong sludges or for leaching the black ash. Such a system requires extensive plant and much labour. (2) Continuous

precipitation, sedimentation, washing, and separation. In the Dorr system, the causticised liquor is passed through a series of thickeners working on the counter-current principle, the sludge being removed by a special device and passed on to the next of the series. Weak wash liquors are disposed of in this system, but it involves much plant, labour, and loss. (3) Intermittent or continuous precipitation, filter-pressing, and washing. After sedimentation and one decantation, the sludge is passed to a filter-press, the liquor being mixed with the decanted liquor. By washing the cake in the press, a weak liquor is obtained, which is disposed of in the usual way. (4) Intermittent or continuous precipitation with continuous filtering and washing. The "Boston tank" for separating liquors from sludge is cylindrical in shape with a conical bottom having a trumpet feed in the centre. The clear liquor flows away through an annular collecting gutter and the sludge, drawn off continuously from a suitable level, is passed on to a rotary continuous filter. By using filter-presses, either intermittent or continuous, there is a great saving of space and labour.—L. A. C.

Ammonia liquor; Manufacture of concentrated—P. Parrish. Gas. J., 1917, 140, 554—556.

IN pre-war times the process in vogue for the manufacture of liquor ammonia involved an initial admixture of milk of lime with the gas liquor to fix the whole of the carbonic acid and hydrogen sulphide. The gases from the still passed through a dephlegmator to obtain an approximately dry ammonia gas which was absorbed in distilled water in three vessels arranged in cascade form. The fixation of the whole of the hydrogen sulphide in this manner would have resulted in serious loss of sulphur compounds and an attendant reduction in the output of sulphuric acid, and consequently the present tendency is to endeavour to desulphurise and decarbonate the liquor by preliminary heat treatment. This is not altogether an easy matter, and results obtained by J. W. Lee showed that 42.1% and 52.6% respectively of the hydrogen sulphide content was removed by the decarbonator, 35.33% and 34.2% respectively being removed by subsequent treatment in a lime purifier. The provision of a subsequent lime purifier is, however, not entirely satisfactory, and a plant capable of removing hydrogen sulphide and carbon dioxide by heat alone would be a great advantage in the by-product industry. The return of the reflux from a lime washer to the fixed ammonia section of the still would (in the case of a plant dealing with 100 tons of crude liquor per day) entail a removal of an extra 2.61 tons of ammonia in addition to the normal amount of 0.25 ton. This necessitates additional steam, and is accompanied by a liability to blockages by calcium sulphide and calcium carbonate. The effective absorption of effluent gases from a decomposer presents difficulties and the author quotes the following calculated analysis of such gases based on a consumption of 100 tons of 1.21% gas liquor per day:—Air, 5.0%; NH_3 , 15.0%; H_2S , 6.1%; and CO_2 , 73.9% by volume. Owing to the absence of any "carrying" gas, the carbon dioxide and ammonia are afforded an opportunity to react, giving rise to possibilities of blockage by deposition of ammonium bicarbonate and other complex compounds. The use of a small quantity of steam as a "carrying" medium has been found advantageous in preventing deposition of sublimate from the gases before they reach the absorbing tower. Pressure in the decomposer should be controlled as it tends to reduce the efficiency of the dissociation. In designing the trays of a decomposer the surface area for the

ascent of the gas and the space for the descent of the liquor should be in proportion to the computed volume of gas at each tray. Cast-iron circular coils are recommended for cooling purposes, steel coils being attacked by the gas liquor, and lead coils being liable to burst. It is advisable to use pure water in the scrubbers after the decomposer. Care should be exercised in filling tanks to minimise loss of ammonia due to displacement of ammoniacal air, and the author recommends that all vents from storage boilers and railway tanks, and the effluent gases from the decomposer be led to one common scrubber of adequate size.—J. E. C.

Ammonia; Manufacture of concentrated and pure liquor—G. A. Hebden. *Coke Oven Managers' Assoc.*, Dec. 15, 1917. *Gas J.*, 1917, 140, 609–610.

"CONCENTRATED ammonia" is a highly concentrated liquor, containing 25% NH_3 and not more than 0.5% H_2S , used in the ammonia-soda process. "Pure liquor ammonia" contains up to 30% NH_3 and no sulphide, phenols, pyridine, or tarry matter. In the manufacture of these products carbon dioxide and hydrogen sulphide are selectively expelled by heating crude gas liquor to about 95° to 100° C. The decomposers are worked on the principle of a continuous ammonia still, direct steam being admitted into the lowest chamber whilst occasionally indirect steam is utilised in the other trays. The crude liquor distilled contains 1.60% free NH_3 , 0.15% fixed NH_3 , 1.7% CO_2 , and 0.24% H_2S . A portion enters the decomposer at the top tray and the other portion, after passing through the first and second condensers, enters about half-way down, a definite economy in steam consumption resulting from this interchange of heat. The temperature at the bottom tray is kept at 100° to 105° C., with a pressure of 10 to 12 lb. per sq. in. The temperature of the gas from the top of the decomposer is kept at about 45° C., any ammonia passing over being retained in water catchers along with a little carbon dioxide and hydrogen sulphide. The ammonia-free gas is then passed through oxide beds. Under the above conditions the CO_2 content is kept below 0.10% and H_2S below 0.03%. The lime is slaked with hot spent liquor, agitated, and after being mixed with the condensed liquid from some of the condensers is pumped into the main still. The top tray of this still is worked under a pressure of 6 lb. per sq. in., and the waste liquor has a content of 0.005% NH_3 . The ammonia vapours pass through three condensers fitted with cast iron cooling coils, cold liquor passing through the first and second coils, cold water through the third. The condensed liquids from the first and second vessel contain 2.5% and 7.4% NH_3 respectively. In making concentrated liquor the condensed liquid and gases from the third condenser pass through absorbers of cast iron, arranged in series, and fitted with cooling coils, any residual gases being absorbed in coke towers fitted with water sprays. The final concentrated liquor contains 25% NH_3 and 0.15 to 0.25% H_2S . In making pure liquor ammonia the gases leaving the last condenser pass through three air-cooled condensers, as it is essential that the gases be dry and at a lower temperature than 15° C. The gases after this additional cooling pass through caustic soda washers to absorb traces of carbonate, then through slaked-lime purifiers to remove hydrogen sulphide. Pyridine, phenols, etc., are extracted in oil washers, and the gases, after passing coke towers to trap any oil in suspension, are led to absorption tanks; these consist of closed iron tanks in series fitted with cooling coils, and arranged in counter-current fashion. The plant described deals with 400 tons

of crude liquor per day, 25 cwt. of lime and 1.8 cwt. of coal being used per ton of liquor.

Water, sodium sulphate, and ammonium sulphate; Equilibria in the ternary system—C. Matignon and F. Meyer. *Comptes rend.*, 1917, 165, 787–789.

THE possible solid phases in this system are ice, anhydrous sodium sulphate, crystallised sodium sulphate, ammonium sulphate, and the double salt $\text{NaNH}_4\text{SO}_4 \cdot 2\text{H}_2\text{O}$, and the following solubilities have been determined:—

I. Solid phase: $\text{Na}_2\text{SO}_4 \cdot (\text{NH}_4)_2\text{SO}_4$:—

Original mixture.	Temp. °C.	Centigram-mols. in 100 grms. of solution.	
		$(\text{NH}_4)_2\text{SO}_4$.	Na_2SO_4 .
Double salt + $2(\text{NH}_4)_2\text{SO}_4$	62.5	27.58	11.50
Na_2SO_4 + excess $(\text{NH}_4)_2\text{SO}_4$	79	29.16	11.15
Double salt + $2\text{Na}_2\text{SO}_4$	79	28.90	—
Double salt + $3(\text{NH}_4)_2\text{SO}_4$	79	28.91	11.56
Double salt	98	30.65	12.23
Na_2SO_4 + excess $(\text{NH}_4)_2\text{SO}_4$	100	30.62	11.27
Na_2SO_4 + excess $(\text{NH}_4)_2\text{SO}_4$	109	31.63	11.35

II. Solid phase: $(\text{NH}_4)_2\text{SO}_4$, double salt :—

Double salt + $(\text{NH}_4)_2\text{SO}_4$..	—19	28.05	2.10
" " " "	—1	28.57	3.34
" " " "	+33	28.58	6.38
" " " "	44	28.83	8.08
" " " "	58	27.70	10.87
Na_2SO_4 + excess $(\text{NH}_4)_2\text{SO}_4$	44.5	28.20	8.06

III. Solid phase: double salt, Na_2SO_4 :—

Double salt + Na_2SO_4	29	10.55	18.46
" " " "	46	18.13	15.08
$(\text{NH}_4)_2\text{SO}_4$ + excess Na_2SO_4	50	21.48	13.73
Double salt + Na_2SO_4	58	25.31	12.34

IV. Solid phase: double salt, $\text{Na}_2\text{SO}_4 \cdot 10\text{H}_2\text{O}$:—

Double salt + $\text{Na}_2\text{SO}_4 \cdot 10\text{H}_2\text{O}$	—13	—	2.98
" " " "	+1	22.02	5.21
$(\text{NH}_4)_2\text{SO}_4$ + excess "	—	—	—
$\text{Na}_2\text{SO}_4 \cdot 10\text{H}_2\text{O}$	+10	18.47	8.22
" " " "	14	16.36	10.46
Double salt + $\text{Na}_2\text{SO}_4 \cdot 10\text{H}_2\text{O}$	14	16.26	10.80
" " " "	25.5	10.06	18.82

V. Saturated solutions of ammonium sulphate, sodium sulphate, and a mixture of the same boil at 108.9°, 102°, and 111° C., respectively, at ordinary pressure, and at these points the solutions have the following concentrations :—

Solid phase.	Temp. °C.	Centigram-mols. in 100 grms. of solution.	
		$(\text{NH}_4)_2\text{SO}_4$.	Na_2SO_4 .
$(\text{NH}_4)_2\text{SO}_4$	108.9	39.22	—
Na_2SO_4	102	—	21.0
$\text{Na}_2\text{SO}_4 \cdot (\text{NH}_4)_2\text{SO}_4$	111	31.75	11.25

—W. P. S.

Orychloride of tin; A new—H. F. Keller. *J. Amer. Chem. Soc.*, 1917, 39, 2354–2356.

AN anhydrous stannous-oxychloride, not apparently previously described, has been found in the centre of a small lenticular mass of tin occurring in the Indian Mounds of Florida. Minute brilliant crystals were observed in cavities in the centre of this mass, about 0.3 gm., of which was collected. The pure material was picked out under a lens and analysed, the result being tin 70.92%, chlorine 21.68%, impurities 0.26%. The formula $\text{SnCl}_2 \cdot \text{SnO}$ is suggested. It appears probable that water containing chloride has gained access to the

cavities through fine holes or fissures and the oxychloride has been very slowly produced by the action of chloride and air.—B. V. S.

Sodium paratungstate; Use of — in the determination of metallic oxides from cyanides. S. B. Kuzirian, J. Amer. Chem. Soc., 1917, 39, 2356—2358.

THE use of sodium paratungstate as a flux in analytical processes (this J., 1911, 800; 1913, 908, 909) has been extended to the determination of cyanides which, in the presence of an oxidising agent, preferably ammonium nitrate, which leaves no residue on fusion, are converted into oxides. The method was checked on a sample of cyanide of which the nitrogen content, chloride equivalent, and potassium content had been previously determined. The cyanide is heated in a crucible with sodium paratungstate, previously ignited to constant weight, a sufficient amount of ammonium nitrate being added to secure complete oxidation. The increase in weight of the paratungstate is then taken. Allowance must be made for carbonates, chlorides, etc., which may be present and which are also converted into oxides in the process.

—B. V. S.

Use of cupferron (phenylnitrosohydroxylamine-ammonium) in:—I. Quantitative separation of zirconium, titanium, iron, manganese, and aluminium. II. Analysis of zircon and baddeleyite. Brown. See XXIII.

PATENTS.

Barium hydrate [hydroxide]; Production of —. C. Deguide, Pas de Calais, France. Eng. Pat. 110,537, July 10, 1917. (Appl. No. 9937 of 1917.) Under Int. Conv., Sep. 29, 1916.

AN intimate mixture of finely powdered barium carbonate (394 parts) with sand or silica (60 parts) or with monobarium silicate (106½ parts) is heated to 1400°—1500° C., dibarium silicate being formed according to the equations:—

The dibarium silicate does not fuse at the temperature of the reaction; on heating with water it forms barium hydroxide and insoluble monobarium silicate, the latter being used again with a fresh supply of barium carbonate.—B. V. S.

Sulphate of ammonia; Manufacture of —. E. V. Evans, and South Metropolitan Gas Co., London. Eng. Pat. 111,309, Sep. 14, 1916. (Appl. No. 13,063 of 1916.)

AMMONIA is passed into hot sulphuric acid, of such dilution that ammonium sulphate does not separate, until the liquor is weakly alkaline. The solution is then filtered and cooled; the ammonium sulphate which crystallises out is practically both white and neutral.—B. V. S.

Calcium chloride; Obtainment of anhydrous —. E. A. Ashcroft, London. Eng. Pat. 111,313, Oct. 19, 1916. (Appl. No. 14,851 of 1916.) Addition to Eng. Pat. 108,920, Sept. 19, 1916 (this J., 1917, 1048).

THE method described in the chief patent for the manufacture of anhydrous magnesium chloride is applied to the calcium salt.—B. V. S.

Sodium sulphite; Manufacture of —. G. L. Crump, and Ekaertlin, Ltd., London. Eng. Pat. 111,314, Apr. 19, 1917. (Appl. No. 11,935 of 1916.)

A MIXTURE of equal weights of sodium sulphate and iron filings, preferably with the addition of about 10% of carbonaceous matter, is heated in an atmosphere of sulphur dioxide.—B. V. S.

Aluminous ores; Process of treating — [to obtain crystalline alumina]. H. A. Richmond, Providence, R.I., Assignor to General Abrasive Co., Inc., Niagara Falls, N.Y. U.S. Pat. 1,245,383, Nov. 6, 1917. Date of appl., Nov. 27, 1916.

ALUMINOUS ores are heated in an electric furnace with a sulphide of a basic metal and carbon. Impurities are driven off as gaseous sulphides and the reduced metal is drawn off in the molten state, leaving a purified crystalline alumina.

—B. V. S.

Hydrogen; Apparatus for manufacturing —. R. E. Brunner, Pittsburgh, Pa. U.S. Pat. 1,246,867, Nov. 20, 1917. Date of appl., May 23, 1917.

IN apparatus for producing hydrogen, the heated gas to be decomposed is passed in series through vertical pipes connected alternately at top and bottom, and water is sprayed downwards into each pipe to remove carbon and other impurities. The water is finally discharged through a liquid seal at the bottom of each pipe.—W. F. F.

Barium hydrate [hydroxide]; Process for obtaining —. C. Deguide, Ixelles, Assignor to D. Marbais, Charleroi, Belgium. U.S. Pat. 1,247,510, Nov. 20, 1917. Date of appl., Mar. 6, 1917.

SEE Eng. Pat. 110,537; preceding.

VIII.—GLASS; CERAMICS.

Silica bricks; Manufacture of —. Philippon. Comptes rend., 1917, 165, 1002—1005.

SILICA bricks were made by grinding silica from different sources with milk of lime for ten minutes and then moulding the product by hand. The bricks were dried on cast iron plates at about 100° C. and were then burned at 1300° C. in a down-draught kiln. Crushing tests were made by placing two half bricks one above the other in the testing machine. Refractoriness tests were made on pieces cut to the same shape and size as standard cones and then heated steadily in a corundum cylinder in a furnace using acetylene and compressed air or oxygen. It was found that the highest crushing strengths were possessed by bricks in which the quartz was most finely ground: bricks made of impalpably fine quartz with 2% lime had a crushing strength of 18 kilos, when dried, and 320 kilos, when burned at 1300° C., but similar bricks made of quartz particles 0.13 mm. diameter had crushing strengths of only 2 kilos, and 16 kilos, respectively. Notwithstanding the differences in the geological origin and physical characters of the various forms of silica used, they all were capable of producing bricks of great strength if the raw material was sufficiently finely ground. The minimum crushing strength of bricks made from impalpably fine quartz was found to be 200 kilos. per sq. cm. The expansion produced on burning the bricks is greatest with those containing large grains. The expansion of bricks made of impalpable quartz is almost nil. The crushing strength of the bricks is increased by the use of relatively large quantities of water in the paste of which they are made. The strength of the dried bricks varies with the proportion of lime present; that of the burned bricks increases with the proportion of lime up to 1%, then remains constant up to 2% and diminishes with still larger proportions. Each 1% of lime lowers the refractoriness by about 20° C. Bricks made of impalpable quartz begin to soften at 800° C.; at 1200° C. they have a crushing strength of 190 kilos. per sq. cm. and 270 kilos. per sq. cm. at 1300° C. Bricks containing larger grains of quartz do not

begin to soften below 1100°C ., but at 1300°C . they have a crushing strength of only 70 kilos. per sq. cm. Tests on bricks made of impalpable quartz mixed with larger grains showed that the most refractory bricks contained the least quantity of impalpable powder and that grains of 8 mm. diameter are the largest permissible in good bricks. On applying the foregoing results to commercial manufacture, it was found best to use material with at least 96% silica, the precise form being unimportant so long as 30% of it is in impalpable powder and 70% in grains of 1–8 mm. diameter. The proportion of lime added was only 0.6% of the bricks, but 2% of the "flour." The bricks fired in a tunnel kiln at 1300°C . had a crushing strength of 200–250 kilos. per sq. cm., an average expansion of 1.6%, a true sp. gr. of 2.4, an apparent sp. gr. of 1.9, and a fusion point of about 1780°C . The bricks have been used for lining a Martin furnace; they have already withstood 200 heats and it is expected that they will withstand more than 300 heats. They are also employed satisfactorily in a number of forges, replacing aluminous bricks.—A. B. S.

PATENTS.

Glass; Opaque semi-translucent — J. J. Miller, Assignor to Macbeth-Evans Glass Co., Pittsburgh, Pa. U.S. Pat. 1,245,487, Nov. 6, 1917. Date of appl., Nov. 10, 1913.

A "SEMI-OPAQUE, semi-translucent" glass is made by fusing a clear-glass batch with compounds of aluminium, fluorine, chlorine, and sulphur. For the last two, a chloride and strontium sulphate are specified.—A. B. S.

Refractory bricks for furnaces; Manufacture of — A. Reynolds, Hove, Sussex. Eng. Pat. 111,355, Dec. 4, 1916. (Appl. No. 17,397 of 1916.)

THE faces or working surfaces of firebricks are heated to such a temperature that the changes which impart coherence or increased refractoriness to the bricks when in use in a furnace may be effected previous to the bricks being required. Each brick is embedded separately in a highly refractory inert material, such as chromite, plumbago, or ground coke and tar, so that only the face to be superheated is exposed, and is then heated until the exposed face has reached the requisite temperature or until the desired changes have been effected to a suitable depth. Bricks, etc., made of materials with a silica: alumina ratio corresponding to the formula SiAl_2O_5 (sillimanite), or with rather more alumina, are heated until incipient fusion occurs at the surface, usually at 1700°C ., the product of the reaction melting at 1850°C . or higher. For foundry-ladle nozzles or stoppers, special devices are needed to prevent the incipiently fused surfaces falling away. For example, a nozzle may be mounted horizontally in a revolving furnace and rotated so rapidly during the superheating that no falling away can occur. Stoppers for steel-casting ladles are conveniently mounted on a rotating rod or screw, similar to the plug-rod of the ladle, and during rotation, the stopper is subjected alternately to heating and cooling so that incipient fusion occurs at its momentarily upper surface, and cooling when the fused portions might tend to fall off.—A. B. S.

Glazed ceramic wares; Process for making — C. Stegmayer, Newark, N.J., Assignor to H. A. Pike, New York. U.S. Pat. 1,245,285, Nov. 6, 1917. Date of appl., Nov. 10, 1911.

CERAMIC articles are made of a body composed of a mixture of common clay and a flux, an engobe of vitrifiable porcelain powder, and a leadless glaze. These materials in the form of powders may be

formed into three layers which are compressed to form the article and are then united by a single firing.—A. B. S.

Kiln. J. P. Williams, St. Louis, Mo., U.S. Pat. 1,245,846, Nov. 6, 1917. Date of appl., Oct. 6, 1913.

A CONTINUOUS kiln (of the Hoffmann type) is heated by means of gas admitted through transverse flues below the floor to air-containing ignition-chambers, combustion being completed among the goods to be burned and above the floor of the kiln. Means are provided for creating a draught horizontally across the ignition-chambers, whereby the ignited mixture of gas and air may be maintained in a state of incandescence and the temperature of the kiln regulated. The lateral gas flues in each chamber are connected to the main annular gas flue by means of portable hoods containing gas-regulating dampers.—A. B. S.

Abrasive; Aluminous — L. E. Saunders and R. H. White, Niagara Falls, N.Y., Assignors to Norton Co., Worcester, Mass. U.S. Pat. 1,247,337, Nov. 20, 1917. Date of appl., Feb. 12, 1917.

AN abrasive material produced in the electric furnace consists of crystalline alumina and 1–15% of iron oxide, but substantially free from silicon and titanium oxides.—W. F. F.

Refractory materials; Manufacture of — N. Levesne, Paris. Eng. Pat. 102,507, Dec. 2, 1916. (Appl. No. 17,289 of 1916.) Under Int. Conv., Apr. 29, 1914.

SEE Fr. Pat. 471,513 of 1914; this J., 1915, 356.

Refractory materials; Process of making basic — C. B. Stowe, Lakewood, Ohio, U.S.A. Eng. Pat. 110,147, Dec. 12, 1916. (Appl. No. 17,865, of 1916.) Under Int. Conv., Oct. 6, 1916.

SEE U.S. Pat. 1,205,956 of 1916; this J., 1916, 1261.

IX.—BUILDING MATERIALS.

Manufacture of silica bricks. Philippon. See VIII.

PATENTS.

Road-treatment. H. H. Hurt, Assignor to Robeson Process Co., New York. U.S. Pat. 1,245,349, Nov. 6, 1917. Date of appl., Jan. 9, 1917.

ROADS are surfaced with a granular material impregnated with a mixture of "wax tailings" and a thinning oil.—A. B. S.

Cement; Manufacture of acid and water-proof — C. C. Meigs, Assignor to Electro-Chemical Supply and Engineering Co., Philadelphia, Pa. U.S. Pat. 1,245,608, Nov. 6, 1917. Date of appl., July 12, 1915.

AN acid salt, such as calcium phosphate, is added to a cement composed of silicious material and sodium silicate, and the mixture is subjected subsequently to the action of an acid which will react with the silica-sodium silicate complex.—A. B. S.

Diatomaceous material and process of making the same. T. M. Caven, Baltimore, Md., Assignor to Maryland Products Co. U.S. Pat. 1,247,503, Nov. 20, 1917. Date of appl., Nov. 4, 1916.

NATURAL diatomaceous silica is transformed into a plastic condition in which it acts as a binder, mixed with a further quantity of the natural diatomaceous silica, and with divided combustible material. The mixture is calcined at such a

temperature that the plastic silica alone fuses, and the combustible material is burned out, leaving the resulting product porous.—W. F. F.

X.—METALS; METALLURGY, INCLUDING ELECTRO-METALLURGY.

[Steel] shoes and dies: *Electric furnace manufacture of* — on the Witwatersrand. *Electric steel-melting plant.* G. H. Stanley and W. Buchanan. J. Chem. Met. Soc., S. Africa, 1917, 18, 72—85.

EXPERIMENTAL and working details are given of a process and plant devised to meet the immediate requirements of the Witwatersrand by melting scrap steel shoes and dies in a non-tilting electric induction furnace of the Kjellin type and re-casting the metal into the required forms. The furnace is constructed of the materials available locally and has a capacity of 1 ton. The available electrical power—2000 volts, 3-phase, 50 cycles—is transformed to give a single-phase current up to 600 amp. at about 12 cycles; the efficiency of the conversion being 60—70%. The power consumption of the furnace is between 800 and 900 kilowatt-hours per ton of steel melted. The monthly output (i.e., net weight of serviceable shoes and dies) increased from 37.2 tons in January to 68.6 tons in August, 1917, the corresponding total costs being £20.0 and £13.8 per ton.

—W. E. F. P.

Copper: The furnace refining of —. L. Addicks. Met. and Chem. Eng., 1917, 17, 579—584.

A NORMAL twenty-four hours cycle for a large modern reverberatory furnace would be about as follows:—Charging and melting, 14 hrs.; blowing, 2 hrs.; skimming, 1 hr.; poling, 2 hrs.; pouring, 5 hrs. Mechanical charging has replaced charging by hand, a novel form of peel consisting of a fork with a special pushing device having proved more successful than the upsetting shovel of the old type. By this means it is possible to charge at the rate of at least 200,000 lb. per hr. "Flapping" or "blowing" is accomplished by blowing compressed air through iron pipes beneath the surface of the molten metal. A small portion of the copper is oxidised to cuprous oxide, which, carried throughout the mass in solution, reacts with any impurities present. The oxidised impurities rise to the top as slag, which is skimmed off through the skimming door. Excess cuprous oxide is generally reduced by poling. Fuel oil, blown beneath the surface, has been tried as a reducing agent, but the method has several objections. Gas might in future be found serviceable for this purpose. During the processes of refining sample buttons are withdrawn from the mass by a ladle, and the shape and structure of these enable the operations to be followed with satisfactory accuracy. For pouring the refined copper into moulds, there are many mechanical devices, among them being the Walker wheel, the Clark machine, the multiple-lip ladle, and the twin ladle. Careful attention must be paid to painting the moulds, bone-ash wash and lampblack giving very satisfactory results. The operation of a reverberatory furnace is very wasteful as regards heat consumption, the efficiency being only about 19%; much of the waste heat, however, can be utilised in waste heat boilers. Great progress has been made in the development of the refining furnace along purely structural and mechanical lines, but there is room for improvement in the system of utilising labour.—L. A. C.

Non-ferrous metals: The electric furnace as a medium for heating —. D. D. Miller. J. Amer. Inst. Metals, 1917, 11, 257—290.

THE electric furnace has been in use for steel making in America for 11 years, and the number of furnaces has increased from 19 in 1913 to 136 in 1917, out of a total of 471 of 17 different makes in use throughout the world, but until the last 3 or 4 years only intermittent attempts have been made to develop similar furnaces for the production of copper and its alloys, such as brass and bronze. At the present time many different types of furnaces are under construction and experiment with a view to commercial use. These include:—The Gillett furnace of the indirect type, General Electric furnace of the combined arc and resistance type, the Conley furnace of the moulded resistor type, the Thomson-Fitzgerald furnace of the resistance type, the Northrup furnace of the induction type, the Hering "pinch effect" furnace, and the Bennett furnace. The furnaces now in actual commercial use for copper-zinc alloys include the Ajax-Wyatt, Foley, Bailly, Rennerfelt, Snyder, and Hoskins furnaces, and some of these are described and working results given. It is considered that the use of the electric furnace for heating and melting of non-ferrous metals will soon be established on a firm commercial basis.—B. N.

Resistance alloys: Electrical properties of some high —. M. A. Hunter and F. M. Sebast. J. Amer. Inst. Metals, 1917, 11, 115—138.

It has been shown that high-resistance alloys must be sought for amongst those combinations in which the metals are present in the form of solid solutions, and that ternary alloys have in general a higher resistivity than binary alloys of similar composition. Amongst binary alloys the highest resistivities are found with nickel-manganese and nickel-chromium alloys, and the highest amongst ternary alloys are shown by ferro-nickel-manganese, ferro-nickel-chromium, and copper-nickel-chromium. Chromium alloys withstand oxidation at high temperatures better than the corresponding manganese alloys. Low temperature-coefficients were found chiefly amongst the copper-nickel-manganese alloys; an increase in the resistivity of an alloy is usually associated with a decrease in the temperature-coefficient, but the two are not strictly parallel, as shown by ferro-nickel and chromium alloys. A series of alloys of copper-chromium are indicated which have relatively high conductivities and high tensile strengths; e.g., alloys containing from 5 up to 17.3 parts of chromium per 100 parts of copper show in the hard drawn state a resistivity of 3.7 to 4.3 microhms per cm. cube and a tensile strength of 84,100—95,400 lb. per sq. in., the corresponding figures for the annealed alloys being 2—2.5 microhms and 55,300—66,500 lb. per sq. in.

—B. N.

Blast-furnace gas cleaning machine: A new —. J. Ruddiman. Met. and Chem. Eng., 1917, 17, 608—611.

THE author describes a device for cleaning, drying, and preheating blast-furnace gas in order to obtain higher temperatures in the blast. In the preheater, hot unscrubbed gas from the furnace passes downwards through flues, imparting its heat to the scrubbed gas, which is conducted through a series of tubes. One type of preheater described acts both as preheater and dust catcher for the hot gas; in another type, it is necessary for the hot gas to have passed through a primary dust catcher, the preheater, however, serving to remove further quantities of dust. From the preheater, the unscrubbed gas passes on to the primary scrubber, which consists of a series of perforated

rotating baffle plates half immersed in water. The nozzles in each baffle are opposite the blank interspaces of the following baffle; thus the gas, impinging on a moist surface, is cooled and scrubbed. Spray pipes between the baffles furnish cooling water in finely divided form. In passing through the water in the lower half of the tank, the plates are cleaned. The gas then passes on to a tower where it is further scrubbed and cooled. In the tower is a central rotating vertical shaft on which are arranged a series of baffles similar to those in the primary scrubber. Sprays of water are supplied between the baffles. The rotation of the baffles imparts a rotary motion to the gas passing up the tower, ensuring thorough cooling, and the water and dirt thrown outwards by centrifugal force, pass downwards between the baffles and the tower, being removed at the bottom. The cool, scrubbed gas passes back into the series of pipes in the preheater and thence through a brick-lined stove main to the burners.—L. A. C.

Process of treating aluminous ores. U.S. Pat. 1,245,383. See VII.

XI.—ELECTRO-CHEMISTRY.

PATENTS.

Electric batteries. H. D. Henry, London, Eng. Pat. 111,383, Jan. 17, 1917. (Appl. No. 860 of 1917.)

IN electric batteries containing a zinc negative element and an acid electrolyte, a preliminary treatment is given to the zinc by placing it in the electrolyte in presence of a fully charged lead dioxide positive plate, discharging the battery through a suitable resistance so as to cause violent action on the surface of the zinc, washing the zinc free from acid, and drying it. It is then amalgamated by applying mercury to the surface, or by dipping it in a solution of a mercury salt. The action of the electrolyte on zinc so treated, when the circuit is open, is reduced to a minimum. The exposed area of the zinc element is reduced so that only so much is sulphated as is necessary for the required amperage. This is found to be about 1-40th of the area of the lead positive plate, and the zinc may be made in the form of a block, cube, or disc, partly covered by an acid-proof impermeable coating so as to reduce the surface to the required extent.—F. Sp.

Insulating compound and process of making same. S. Satow, Sendai, Japan. U.S. Pat. 1,245,980, Nov. 6, 1917. Date of appl., Dec. 30, 1916.

AN insulating compound is produced by mixing formaldehyde and a fibrous body with a liquid, adhesive, glue-like mass of glutinised vegetable proteins.—F. Sp.

Electrolytic cells. F. G. Wheeler, Appleton, Wis., U.S.A. Eng. Pat. 102,949, Oct. 24, 1916. (Appl. No. 15,137 of 1916.) Under Int. Conv., Oct. 30, 1915.

SEE U.S. Pat. 1,236,025 of 1917; this J., 1917, 1053.

XII.—FATS; OILS; WAXES.

Copra; Experiments on the preparation of.—in Java. M. B. Smits, Teysmannia, 1916, 27, 495—501. Bull. Agric. Intell., 1917, 8, 1253.

IT was found that 500 very ripe coconuts weighing 844.35 kilos, yielded 127.15 kilos, of copra, whilst 500 nearly ripe nuts weighing 952.86 kilos, gave 128.75 kilos, (i.e., 150 grms. and 135 grms. per kilo, respectively). There was also no material difference between the yields from nuts picked near the coast and those collected inland. The variety of nuts known as "kerambil sirah" gave a much better yield, both of copra and oil, than the variety "kerambil idjau," which is also common in Java.—C. A. M.

Catalytic hydrogenation [of oils]; Influence of carbon monoxide on the velocity of —. E. B. Masted. Faraday Soc., Dec., 1917, 7 pages.

ESPECIAL interest attaches to the effect of carbon monoxide on the catalytic hydrogenation of oils, owing to the fact that hydrogen prepared commercially from water-gas usually contains a small amount of carbon monoxide. In the experiments described, pure neutral olive oil was hydrogenated in a vessel which was mechanically agitated in an oil-bath maintained at 180° C. The hydrogenation vessel was charged with 10 grms. of the oil and a catalyst containing 0.1 gm. of nickel, and, after being exhausted by means of a Geryk pump, in successive experiments pure hydrogen and hydrogen containing from 0.25 to 2.0% of pure carbon monoxide respectively were admitted and the amounts of absorption were measured by reading the volumes of gas left in burettes connected with the hydrogenation vessel. It was found that when the hydrogen contained as little as 0.25% of carbon monoxide, hydrogenation for several hours was necessary to introduce into the oil the same volume of gas as was absorbed in one hour in the case of pure hydrogen. The first traces of carbon monoxide are relatively the most poisonous, and the inhibitive effect of successive increases in the proportion of carbon monoxide decreases with the rise in the proportion. The toxic action of carbon monoxide may be distinguished from the diluting action of any foreign gas which merely obstructs the hydrogenation. This diluting effect may be calculated theoretically, and the result deducted from the total effect experimentally determined.—C. A. M.

Fir seed oil. J. Prescher. Pharm. Zentralh., 1917, 58, 533—534.

FIR SEEDS yield a clear yellow drying oil having the following physical and chemical characters:—sp. gr., 0.925; refractometer reading at 25° C., 78.2; iodine value, 155.8; saponif. value 182.6; acid value, 0.8; Reichert-Meißl value, 1.2. The seeds contain about 33% of oil on the dry substance.—W. P. S.

Iodine value of oils and fats; Comparison between the bromide-bromate method and the methods of Hübl and of Wijs for the estimation of the —. C. Kelber and H. Rheinheimer. Arch. Pharm., 1917, 255, 417—424.

COMPARATIVE experiments on the estimation of the iodine value of certain fats and oils by Gäbel's method (Arch. Pharm., 1912, 250, 72) and by the methods of Hübl and of Wijs led to the following conclusions. Oils and fats with small iodine values, including hydrogenised oils which before hardening had large iodine values, give concordant results by all three methods provided that a sufficiently long time is allowed for the action of the halogen solution. Oils with large iodine values yield trustworthy results by the methods of Hübl and Wijs; the bromide-bromate method, however, always gives too low results in these cases. The authors prefer Wijs' method to that of Hübl on account of the stability of the solution and the shorter time required for the estimation.—C. S.

Comparative keeping qualities of palm-kernel, coconut, ground nut [arachis], and other oil-cakes. Godden. See XIXA.

Comparative digestibility of palm-kernel cake, extracted palm-kernel meal, and undecorticated cottonseed cake. Crowther and Woodman. See XIXA.

PATENTS.

[Hydrogenising] oils; Process and apparatus for treating —. C. Ellis, Montclair, N.J. U.S. Pat. 1,247,095, Nov. 20, 1917. Date of appl., May 2, 1917.

THE apparatus consists of a reaction vessel connected with a number of gas-holders by means of pipes and valves. Hydrogen is passed from one of the gas-holders to the reaction vessel containing the oily material and catalyst, the once-used unabsorbed gas being collected in a separate gas-holder. The once-used hydrogen is passed into the reaction vessel a second time and the unabsorbed gas is collected in yet another separate gas-holder. Such partial absorptions and collections of unabsorbed gas are continued until the desired hydrogenation has been effected. A heat-economising device is provided enabling a transference of heat units to take place between gas leaving the reaction vessel and that entering.

—A. DE W.

Oily materials; Process of treating — preparatory to hydrogenation. C. Ellis, Montclair, N.J. U.S. Pat. 1,247,516, Nov. 20, 1917. Date of appl., Mar. 15, 1915.

OILY material containing substances inimical to the activity of a nickel catalyst is treated with a finely divided "detoxicating material" containing copper hydroxide. The copper hydroxide and absorbed "catalyst poisons" are then removed from the oil, which is afterwards mixed with nickel catalyst and hydrogenised in the usual way.

—A. DE W.

Coconut oil; Process for the extraction of —. G. G. Turner, New York, and C. H. Leighton, Brooklyn, N.Y. U.S. Pat. 1,247,597, Nov. 20, 1917. Date of appl., Apr. 21, 1917.

COCONUT oil is obtained from copra or the like by soaking the finely comminuted "meat" in a solution of sodium chloride of at least 3% strength, with agitation, until the oil is completely separated from the remaining material. The oil, together with a part at least of the other material, is separated by sedimentation and is passed through a centrifugal specific gravity separator and finally clarified.—A. DE W.

XIII.—PAINTS; PIGMENTS; VARNISHES; RESINS.

PATENTS.

Coloured calcimines [distempers]; Preparation of ingredients for the production of —. A. B. Merry, Springfield, Mass., Assignor to The Cott-A-Lap Co., Semerville, N.J. U.S. Pat. 1,247,128, Nov. 20, 1917. Date of appl., Mar. 27, 1914. Renewed Oct. 1, 1917.

A COLOURED calcimine is made and preserved ready for use by preparing units of calcimine body material and separate units of colour material differing if necessary as to colour, the calcimine units and colour units being kept separate until shortly before use. The units may be in the form of solid tablets.—A. DE W.

Lacquer and process of making same. Lacquered product and process of making same. S. Satow, Sendai, Japan. U.S. Pats. (A) 1,245,981 and (B) 1,245,982, Nov. 6, 1917. Dates of appl., Dec. 30, 1916, and Feb. 1, 1917.

(A) A LACQUER is produced by "glutinsing" vegetable proteins with a phenol to form a liquid.

adhesive, glue-like mass, and treating it with an active methylene compound, *e.g.*, formaldehyde, controlling the consistency if necessary with benzene. (B) Brick, cement, tile, or similar substances are shaped without heat, and the surfaces, preferably after the removal of air, are coated with a glaze consisting of a liquid, adhesive, glue-like mass produced by condensing vegetable proteins with an active methylene compound.

—F. Sp.

Linoleum-like substance and process of making same. S. Satow, Sendai, Japan. U.S. Pat. 1,245,978, Nov. 6, 1917. Date of appl. Dec. 11, 1916.

A LINOLEUM-LIKE substance is produced by glutinising vegetable proteins, incorporating with the mass a filler containing cork dust, and rolling the product on to a fabric.—F. Sp.

XIV.—INDIA-RUBBER; GUTTA-PERCHA.

PATENT.

Rubber substitute and process of making same. S. Satow, Sendai, Japan. U.S. Pat. 1,245,979, Nov. 6, 1917. Date of appl. Dec. 11, 1916.

A RUBBER substitute is produced by mixing glutinised vegetable proteins and vulcanised oil, or by mixing glutinised vegetable proteins with a phenol, an oxidising oil, an active methylene compound, and an alkali, and vulcanising the product.—F. Sp.

XV.—LEATHER; BONE; HORN; GLUE.

PATENTS.

Artificial leather and process of making same. S. Satow, Sendai, Japan. U.S. Pat. 1,245,977, Nov. 6, 1917. Date of appl. Dec. 11, 1916.

ARTIFICIAL leather is produced by mixing together "glutinised" vegetable proteins, cellulose derivatives, a sticky viscid substance, fibrous material, a condensing agent, and an alkali.—F. Sp.

Proteidal [plastic] composition and process of making same. S. Satow, Sendai, Japan. U.S. Pat. 1,245,984, Nov. 6, 1917. Date of appl. May 17, 1917.

VEGETABLE proteins are separated from material containing them, then "glutinised," and mixed with the residue of the material from which they were separated to form a plastic composition.—F. Sp.

Binding and cohering composition. U.S. Pat. 1,247,595. See I.

XVI.—SOILS; FERTILISERS.

Ammonification [in soils]; Influence of the chemical structure of the compounds to be ammonified upon the rate of— K. Miyake. J. Amer. Chem. Soc., 1917, 39, 2378—2382.

THE rates of ammonification of leucine, tyrosine, acetanilide, benzanilide, acetamide, and benzamide in five different soils were observed. The soils were air-dried and sifted and then mixed with the compound and water in the proportion of 100 grms. of soil, a quantity of the compound equivalent to 100 mgrms. of nitrogen, and 10 c.c. of water. Samples were withdrawn at intervals up to 16 days and the ammonia produced determined by distillation with magnesia. The average figures of the highest amounts of ammonia produced (in mgrms. of ammonia-nitrogen from 100 mgrms. equivalent nitrogen per 100 grms.

of soil) were as follows:—acetamide, 88.36; leucine, 76.46; tyrosine, 59.28; benzamide, 8.07; acetanilide, 5.28; benzanilide, 5.30. The variation among the soils was considerable, the extreme figures, *e.g.*, for acetamide being 71 and 95.5 and for benzanilide a trace and 14. The author concludes that fatty compounds are more easily ammonified than aromatic compounds, and compounds containing the amino group more easily than those containing the amino group.—B. V. S.

Nitrogen transformations in soils; Influence of sodium nitrate upon— with special reference to its availability and that of other nitrogenous manures. D. A. Coleman. Soil Sci., 1917, 4, 345—432.

A VERY full historical review of the literature is given and the results referred to are discussed to some extent. The influence of sodium nitrate upon nitrogen transformations in soils, as shown by its effect upon the ammonifying, nitrifying, and nitrogen-fixing powers of seven types of soil, has been studied. Applications of sodium nitrate markedly increased the simplification of protein substances applied to the soil, the increase varying with the organic substance used, cottonseed meal being ammonified to a greater extent than dried blood. Acid phosphate (superphosphate) increases the ammonification of dried blood nitrogen but potash in the form of potassium chloride has very little effect. In alkaline soils sodium nitrate loses to a large extent its stimulating effect owing to an increase in the numbers of bacteria which assimilate the simplified material and also owing to a rearrangement of the soil flora. Of the soil flora studied, the fungi respond most to the application of sodium nitrate, and the bacteria next, the stimulating effect being due to the anion. Sodium nitrate at first stimulates the nitrification of dried blood, cottonseed meal, and, to a lesser extent, of ammonium sulphate, but when present in large quantities it depresses nitrification. The same is true of its effect on nitrogen fixation by azotobacter. For dressings up to 5000 lb. per acre, the effect of sodium nitrate on the activity of nitrobacter is the same as on that of nitrococcus, but with larger dressings the activity of nitrobacter is inhibited. The action of this salt is thus most adverse towards the nitrogen-fixing bacteria, less detrimental to the nitrifying group, and still less to the ammonifying group. As applied in agricultural practice it generally enhances the activity of the two latter groups, whilst depressing the activity of the first group of organisms.—W. G.

Farmyard manure; Changes taking place during the storage of— E. J. Russell and E. H. Richards. J. Agric. Sci., 1917, 8, 495—563.

THE variation of the dried matter and combined nitrogen occurring during storage of farmyard manure under various conditions was investigated. It is shown that, owing to an oscillation between aerobic and anaerobic conditions in the heap, considerable loss of nitrogen in the free state occurs. The authors explain this loss of free nitrogen on the general hypothesis that, under anaerobic conditions, molecular groupings tend to arise which become unstable as soon as aerobic conditions set in, and *vice versa*. It is known that, on the entry of air, certain carbon compounds formed under anaerobic conditions may be converted into compounds with shorter chains, by the elimination of CH_4 , and it is suggested that some complex nitrogen compound may be converted into a simpler compound by elimination of nitrogen. Alternate nitrification and denitrification in the heap is but a special case of this. The conditions to be aimed at in storing farmyard

manure are complete anaërobic conditions, preferably at 26° C., and further experiments on the practical side are in progress in connection with this point.—W. G.

Fumigation with hydrocyanic acid: Studies in greenhouse—, *Physiological effects on the plant*. W. Moore and J. J. Willaman. *J. Agric. Res.*, 1917, 11, 319—338.

THE presence of hydrocyanic acid in the plant after fumigation was proved by grinding up the tomato plants used, adding 5% tartaric acid solution, and slowly distilling off any hydrocyanic acid into caustic soda. As much as 9.01% of hydrocyanic acid in the dry plant was present in some cases, and this caused severe injury to the plant. The acid gradually disappeared within a few hours in all cases. The immediate effect of the presence of the acid in the plant was a sudden reduction in the oxidase and catalase activity after fumigation, followed by a fairly rapid and permanent recovery. Resulting from these respiratory changes, there was an inhibition of photosynthesis and of the translocation of starch, which required several days for complete restoration. There was also an increased permeability in the leaf septa and a more rapid cuticular respiration, which led to wilting of the plant; if the fumigation had been severe, the wilting was permanent and the plant died. There was a stimulation of growth in those plants which had been fumigated without injury and an increase in the yield of fruit. No change was found in the chemical composition of the plants as a result of the fumigation.—J. H. J.

Hydrocyanic acid gas as a soil fumigant. E. R. de Ong. *J. Agric. Res.*, 1917, 11, 421—436.

EXPERIMENTS were made to determine the relation between the least dose of hydrocyanic acid which was toxic to insects and the largest dose which was non-toxic to plants. The physical and chemical action of the gas in soil was also investigated. A solution of 1 gm. of sodium cyanide in 1 litre of water acidified with dilute sulphuric acid, when placed in an enclosed space, caused the air of the space to contain 0.3% of hydrocyanic acid. Other strengths of hydrocyanic acid in air were prepared similarly, and various insects placed in the air space. 0.0046% of the gas in air was the least toxic amount for the house fly, whilst beetles required 0.0365%, 0.0046% of the gas also retarded the germination of lettuce seed, although the seeds were not killed by much higher concentrations. Seedlings were not affected by treatment twice as strong as the toxic dose for flies, and cuttings were very much more resistant. For experiments with soil, it was found necessary to generate the gas in the soil from sodium cyanide and sulphuric acid. Water and soil absorbed the gas very strongly, and the variability of the absorption by soils of varying characters prevented any determination of the amount necessary to destroy insects and at the same time be safe for plants. A sandy soil took up the gas in proportion to the water present, but in a clay soil the gas entered into combination with the soil constituents or else was adsorbed by the soil particles. The gas diffused very slowly in wet soils, but fairly rapidly in moist soils. It proved satisfactory as a fumigant for porous soil, seed beds, and potting soil.—J. H. J.

XVIII.—FERMENTATION INDUSTRIES.

Wine: Separation and determination of lactic, succinic, and malic acids in—, J. Laborde. *Comptes rend.*, 1917, 165, 793—795.

Dry wines. Fifty c.c. of the wine is neutralised with potassium hydroxide solution, 5% mercuric acetate solution is added in quantity just sufficient

to precipitate the tannins, the mixture is heated at 50° C., filtered, and the precipitate washed twice with warm water. To the filtrate is added a quantity of N/1 sulphuric acid equal to the amount of alkali used for the neutralisation plus a further amount equivalent to the difference between the total alkalinity of the ash expressed as potassium bitartrate and the alkalinity of the potassium bitartrate corresponding with the total tartaric acid present. The solution is then evaporated to a syrup, water is added, and the evaporation repeated. The residue is treated with animal charcoal (2 grms.), sand, and 25 c.c. of 95% alcohol, and extracted with ether (50 c.c.), the extraction being twice repeated with 15 c.c. of a mixture of equal volumes of alcohol and ether. The extracts are filtered, the filtrate is evaporated to a few c.c., and this residual solution is treated with 0.2 gm. of animal charcoal and 10 c.c. of water, and filtered. The filtrate is neutralised, while boiling, with alkali solution (calcium hydroxide solution), evaporated to 8 c.c., 1 drop of 50% acetic acid is added, followed by 90 c.c. of warm 95% alcohol. The mixture is heated to boiling and the precipitated calcium malate and succinate are filtered off and washed with hot 85% alcohol; a determination of calcium in the filtrate gives the quantity of lactic acid present. The precipitate is then dissolved in boiling water (a small amount of calcium phosphate may remain insoluble), the solution is evaporated to 8 c.c. and treated with 1 c.c. of glacial acetic acid and 90 c.c. of 95% alcohol. The mixture is boiled and the precipitated calcium malate is collected and washed with 85% alcohol acidified with acetic acid. Determinations of calcium in the precipitate and filtrate, respectively, give the quantities of malic and succinic acids present. If citric acid is contained in the wine it is precipitated with the malic acid. *Sweet wines*. After removal of tannins and treatment with sulphuric acid, the solution is evaporated to a syrup, 10 to 20 c.c. of alcohol is added and the mixture is extracted with 50 c.c. of ether. After the ethereal layer has been decanted, the extraction with alcohol and ether is repeated once or twice. The extracts are then evaporated and the residue used for the determinations as described. Normal wines contain about 0.70 gm. of succinic acid per litre; the quantities of lactic and malic acids vary considerably according to the origin and quality of the wine.—W. P. S.

XIXA.—FOODS.

Milk and butter: Enzymes of—, R. W. Thatcher and A. C. Dahlberg. *J. Agric. Res.*, 1917, 11, 437—450.

IN the case of milk it was found that the use of 1% of chloroform to prevent bacterial action prevented proteolysis also, and the same result was brought about by 15% of sodium chloride. In following the protease in fresh milk through the process of butter making, it was found that protease was slightly increased in the separated cream and was highly concentrated in the separator slime, and, in general, the protease increased along with the increase in the proportion of

casein nitrogen in the total nitrogen. In butter the protease cannot act because of the high salt content. The activity of any lipase in butter was too small to be accurately measured. No oxidase could be found in milk and butter, and the amount of peroxidase was very small. Catalase was present in milk and butter. The enzyme content of butter was very small on account of the high dilution with fat, and it is concluded that enzymic action is not a factor in the deterioration of butter in cold storage.—J. H. J.

Palm-kernel cake; Influence of — upon the composition of milk-fat. C. Crowther and H. Woodhouse. J. Agric. Sci., 1917, 8, 451—454.

PALM-KERNEL cake at the rate of 2 lb. per head per day was fed to cows at grass. Samples of the milk-fat from each cow were taken twice a week and the following determinations made thereon:—Koettstorfer (saponification) value; Reichert-Wollny value; Polenske value; iodine absorption, and refractive index. The results with each cow show a rise in the first three values and a fall in the iodine absorption and refractive index, as an apparent consequence of feeding with palm-kernel cake. The differences in the cases of the Reichert-Wollny and Polenske values were, however, small in comparison with the probable errors.—W. G.

Palm-kernel, coconut, ground-nut [arachis], and other oil-cakes; Comparative keeping qualities of —. W. Godden. J. Agric. Sci., 1917, 8, 419—428.

PALM-KERNEL, coconut, and ground-nut cakes were compared with linseed, undecorticated cottonseed, "soycot," and soya cakes. So far as keeping properties are concerned, palm-kernel cake compares favourably with most of the oil-cakes commonly used on farms. During storage under ordinary farm conditions the only change which occurs is one common to all the oil-cakes examined, namely, an increase in the free fatty acid content of the oil. During incubation in a moist state at 37°C., on only four of the cakes examined, namely cottonseed, ground-nut, "soycot," and soya cakes, was there any marked development of moulds, this being accompanied by a loss of organic matter, the loss being distributed between the oil and the soluble carbohydrates of the cake. Dry storage is essential to prevent moulding and the consequent loss of organic matter.—W. G.

Palm-kernel cake, extracted palm-kernel meal, and undecorticated cottonseed cake; Comparative digestibility of —. C. Crowther and H. E. Woodman. J. Agric. Sci., 1917, 8, 429—447.

Two kinds of palm-kernel cake, one of cottonseed cake, and one of palm-kernel meal, were fed in turn to two sheep on a basal ration of "seeds" hay, and from the experimental results the following digestion coefficients were calculated, making due allowance for the presence of metabolic products in the faeces:

	Undecort. cotton- seed cake.	Palm kernel cake.	Extracted palm kernel meal.
	%	%	%
Organic matter	55.0	70.8	76.7
Crude protein	67.4	75.4	79.2
Crude protein (corrected) ..	74.7	88.5	90.0
Ether extract	(100 ?)	98.2	96.3
Nitrogen-free extractives ..	62.0	78.6	86.0
Crude fibre	34.6	20.6	44.8

—W. G.

Yeast; Digestibility of dried —. C. Crowther and H. E. Woodman. J. Agric. Sci., 1917, 8, 448—459.

THE digestion coefficients obtained with a "low-grade" sample of dried yeast fed to sheep along with "seeds" hay were:—organic matter, 93.5%; crude protein, 96.6%; true protein, 96.6%; nitrogen-free extractives, 96.9%. Owing to the very small proportions of ether extract and crude fibre in the dried yeast, it was not possible to measure the digestibility of these ingredients.—W. G.

Cocoa powders; Examination of — for the content of husks. O. Keller. Arch. Pharm., 1917, 255, 405—416.

ALL cocoas examined by the author during the last six months have been adulterated with husks, and a simple, trustworthy method of estimating the latter is very desirable. The author criticises various chemical and mechanical methods which have been proposed and describes in some detail a method based on his observations that the ethereal extract of pure cacao kernels is colourless or faintly yellow whilst the extract of the husks is distinctly brown (Apoth.-Zeit., 1915, 560). Two grams of the cocoa powder and 15 c.c. of ether, are frequently shaken for 24 hours in a well-stoppered vessel at the ordinary temperature, the shaking being discontinued during the last 2 or 3 hours. Ten c.c. of the supernatant liquid is pipetted into a test-tube and filtered through kieselguhr, repeatedly if necessary, until a clear filtrate is obtained, into one comparison tube of a colorimeter. The test-tube and filter are washed with so much ether that after the washings have been added to the solution in the comparison tube the liquid has a depth of 5 cm. The second comparison tube contains water having a depth of 5 cm. and to it is added ferric chloride (the liquid must be freshly prepared from officinal *liq. ferri sesquichlor.* and contain 0.1 grm. of iron in 100 c.c.) until the colours of the liquids viewed from above have the same strength. The comparison is repeated, with the difference that the quantity of water is diminished by a volume equal to that of the ferric chloride solution added. The volume of ferric chloride solution required increases with the husk content of the powder. Pure cocoa powder containing 51% of fat requires 2.4 c.c. of the ferric chloride solution; pure husk-free powder requires 1.4 c.c.; pure husks require at least 3.5 c.c., the average value being 4.4 to 4.5 c.c. The author is of opinion that powders containing 20% or more of fat and requiring 2.5 c.c. or more of the ferric chloride solution have been adulterated with husks.—C. S.

PATENTS.

Condensed buttermilk and buttermilk powder; Process and apparatus for the production of —. E. C. R. Marks. London. From Merrell-Soule Co., Syracuse, N.Y., U.S.A. Eng. Pat. 111,340, Nov. 24, 1916. (Appl. No. 16,857 of 1916.)

BUTTERMILK is concentrated by causing it to flow, by centrifugal action, upwards in the form of a thin layer over the interior walls of a heated vertical cylinder from which the air is exhausted. The concentrated buttermilk escapes from the top of the cylinder and, after passing through a heating coil, is atomised into a chamber, a current of dry air also being introduced into the chamber.—W. P. S.

Milk; Modified — [for infants]. E. C. R. Marks. London. From Merrell-Soule Co., Syracuse, N.Y., U.S.A. Eng. Pat. 111,341, Nov. 21, 1916. (Appl. No. 16,859 of 1916.)

THE modified milk is obtained by mixing milk,

cream, and whey in suitable proportions, *e.g.*, 270 lb. of milk containing 3.5% of fat, 45 lb. of cream containing 26% of fat, and 1000 lb. of whey are mixed. The mixture is sterilised at 180° F. (82° C.), and converted into a dry powder by atomising it into a current of dry air. The resulting powder contains approximately: fat 18, lactose 57.8, casein 8.6, lactalbumin 7.5, ash 7.3, and water 1.2%, and is composed of spherical particles practically devoid of bacteria but containing active enzymes.—W. P. S.

Canning: Process of —. K. Miyauchi, Kago-shima-Ken, Japan. U.S. Pat. 1,245,489, Nov. 6, 1917. Date of appl., Apr. 23, 1917.

A LAYER of "degutinated" and deodorised wood shavings is placed over the interior surface of the tin receptacle so as to prevent the contained substance from coming into contact with the metal.—W. P. S.

Protein matter from maize: Process of obtaining —. J. Takamine, New York, and S. Satow, Sendai, Japan. U.S. Pat. 1,245,818, Nov. 6, 1917. Date of appl., Nov. 25, 1916.

GROUND maize is cooked and the gelatinised starch is saccharified; the mass is then fermented and distilled. The proteins are separated from the residual liquid, dissolved in an alkali solution, and then precipitated by the addition of an acid.

—W. P. S.

XIXB.—WATER PURIFICATION; SANITATION.

Water; Identification and determination of zinc in —. R. Meldrum. Chem. News, 1917, 116, 295—296. 308—310.

The ferrocyanide reaction may be used for the detection and determination of zinc in water; it is capable of detecting 1 part of zinc in 1 million parts of water. One hundred c.c. of the water is acidified with 1 c.c. of 20% hydrochloric acid in a glass cylinder and, after 1 min., 1 c.c. of 1% potassium ferrocyanide solution is added. An opalescence appears within 20 mins. if zinc is present and the quantity of the metal is found by comparison with standards containing known amounts of zinc. In preparing the standard zinc solutions, the same kind of water as the sample, but free from zinc, must be employed, since the sensitiveness of the test is influenced by the salts, etc., present. If a quantity of the water cannot be obtained before it is contaminated with zinc, an artificial water may be prepared of corresponding composition as regards saline substances. When distilled water is used the results may be from 50 to 100% too high. (See also this J., 1918, 19 A.)

Sewage and its precipitation. R. Brown. Soc. of Engineers, Nov. 19, 1917. [Reprint.] 12 pp.

EXPERIMENTS on the large scale, extending over about a fortnight in each case, were made with three precipitants: (1) lime, (2) ferric sulphate solution and lime, (3) aluminium sulphate and lime. The sewage treated was acid from acetic acid and passed through a detritus tank before the precipitant was added; afterwards it passed through a continuous-flow precipitation tank. The amounts of the precipitants used per gallon were: 7.6 grains of lime, 2 grains of ferric sulphate plus 4 grains of lime, and 1.88 grains of aluminium sulphate plus 2.8 grains of lime. The percentage purification obtained varied from 35 to 49 in oxygen absorption, 33 to 43 in albuminoid ammonia, 70 to 78 in suspended solids, and 21—27 in colloids; in each case the highest figures were given by aluminium sulphate and lime. The

results obtained with ferric sulphate solution and lime were about the same as those previously obtained by the author with solid ferric sulphate and lime.—J. H. J.

PATENTS.

Sewage; Treatment of — for the purification thereof and the production of combustible gas therefrom. H. Flicker, Parramatta, N.S.W. Eng. Pat. 111,401, Feb. 27, 1917. (Appl. No. 2893 of 1917.)

THE sewage, together with a regulated quantity of air, is admitted into the upper part of a closed tank, sprinklers distributing the incoming liquid over the surface of sewage already contained in the tank. The tank is provided with a sludge pit and with a partition extending to the surface of the sludge, the liquid passing below this partition on its way to the exit from the tank. The upper portion of the sludge is thus disturbed and accumulated gases are liberated. The gases resulting from the decomposition of the sludge are collected at the top of the tank and may be utilised for heating water to raise the temperature of the contents of the tank when necessary in order to accelerate bacterial action.—W. P. S.

House waste and sewage; Method of and apparatus for treating —. E. L. McGill, New York. Eng. Pat. 111,422, Apr. 18, 1917. (Appl. No. 5469 of 1917.)

THE sewage is delivered into the first of a series of covered tanks situated on an incline so that the liquid may pass from one to another. Longitudinal partitions near the sides of the tanks form channels which are filled with sand up to the level of the liquid in the central part. The liquid passes under the lower edges of the partitions, rises upwards through the sand, and is discharged on to a sand filter and thence into a stream or over land. Raking devices are provided for agitating the sand in the channels, and air is circulated through the tanks. The tanks may be arranged in parallel series so that one set may be in use while the other set is being cleaned.—W. P. S.

Sewage and analogous liquids; Purification of —. W. Jones, Stourbridge. U.S. Pats. 1,247,540—1,247,543, Nov. 20, 1917. Dates of appl., Oct. 9, 1914, Sept. 13, Oct. 18, and Oct. 18, 1915.

SEE Eng. Pats. 22,952 of 1913, 1141 of 1915, and 22,737 and 22,736 of 1914; this J., 1915, 244; 1916, 326, 195.

XX.—ORGANIC PRODUCTS; MEDICINAL SUBSTANCES; ESSENTIAL OILS.

Tobacco; Effect of some alkaline salts upon the fire-holding capacity of —. H. R. Kraybill. Bot. Gazette, 1917, 64, 42—56. Bull. Agric. Intell., 1917, 8, 1256—1258.

TOBACCO leaves were sprayed with 28.9% solutions of the respective salts, and, after being left under a bell jar, pieces were cut from the tip, middle, and base of each leaf, and the duration of their combustion determined. The results showed that the carbonates of caesium, rubidium, and potassium have a pronounced effect on the fire-holding capacity of tobacco, whereas the carbonates of lithium and sodium have not this effect. Of the oxalates tried only potassium oxalate had any effect. Potassium citrate also promotes the

burning properties, but the citrates of sodium and lithium have practically no action. Organic salts of potassium, tripotassium phosphate, dipotassium phosphate, and potassium sulphate promote the combustion, but the chloride, acid sulphate, and monopotassium phosphate have a bad effect. The favourable action of potassium salts is not due to their reduction, nor is the injurious effect of chlorides due to their melting, but it seems probable that the favourable salts may have a specific catalytic action upon the combustion, whilst chlorides have a negative catalytic action. Possibly the effect of salts in raising the temperature may also play a part in the process.—C. A. M.

Uzara root; Chemical constituents of —. W. Hennig. Arch. Pharm., 1917, 255, 382—405.

UZARA root is of medicinal value on account of its anti-diarrhetic properties. The drug is procurable under the name "uzaron," which is the dried alcoholic extract of the root. From uzaron the author has isolated two glucosides having different physiological effects, one of which is amorphous and is present in very small amount, whilst the other, *uzarin*, $C_{25}H_{108}O_{30} \cdot 9H_2O$, forms colourless needles, m.pt. about $210^{\circ}C$, decomp. about $200^{\circ}C$. On hydrolysis uzarin yields propyl alcohol, dextrose, and uzaridin, $C_{15}H_{24}O_5 \cdot 4H_2O$, colourless leaflets, decomposing about $246^{\circ}C$ (anhydrous), the last substance being partly changed to anhydrous uzaridin, $C_{15}H_{22}O_4 \cdot 4H_2O$, colourless needles, decomp. about 208° — $214^{\circ}C$ (anhydrous). Uzaridin forms a triacetyl derivative, needles, m.pt. 225 — $227^{\circ}C$. —C. S.

Fruit of Asparagus officinalis. L. N. E. Hehner. Chem. News, 1917, 116, 296—297.

THE red berries of this plant contain:—Reducing sugars, 36.12; oil, 1.08; proteins, 9.75; ash, 3.5%. Malic acid is present in large amount, together with a trace of citric acid, but tartaric and oxalic acids are absent.—W. P. S.

Iron; Determination of metallic — in Ferrum reductum. A. Eberhard. Arch. Pharm., 1917, 255, 357—381.

THE author finds that the simple method described by Winkler (Z. angew. Chem., 1917, 64) is not trustworthy, since the increase in weight of the sample does not attain a constant value even after the ignition in air for 15—20 minutes has been repeated five or ten times; moreover, by the prolonged ignition the triferic tetroxide originally present in the *ferrum reductum* is partially converted into ferric oxide, with the result that the percentage of metallic iron found is too high. The author has examined the official methods adopted in different countries. He recommends that, in addition to the total iron, the metallic iron be estimated by Merck's mercuric chloride method; 25 c.c. of the filtrate should be used, the solution of potassium permanganate should be dilute (2—2.5 grms. per litre), and the confirmatory iodometric estimation may be omitted. The author has examined a method suggested by Schmidt, in which bromine instead of iodine is used for the solution and estimation of the iron. The method fails on account of the unavoidable loss of bromine vapour during the estimation.—C. S.

PATENTS.

Blood-coagulating substance; Manufacture of a —. O. Inray, London. From Soc. of Chem. Ind. in Basle, Switzerland. Eng. Pat. 111,533, Nov. 30, 1916. (Appl. No. 17,218 of 1916.) Addition to Eng. Pat. 11,215 of 1915 (this J., 1916, 72).

[SEE Ger. Pat. 296,678 of 1916; this J., 1917, 615.

An alternative process consists in mixing an alcoholic extract of the blood with water and then extracting with an organic solvent, other than a chlorinated hydrocarbon, e.g., ether, benzene, or toluene. The original process or any of the modified processes may be applied directly to freshly drawn blood.

Opium; Product derived from — and process of making same. A. Gams, Assignor to Soc. of Chemical Industry in Basle, Switzerland. U.S. Pat. 1,243,729, Oct. 23, 1917. Date of appl. Mar. 24, 1917.

OPIMUM extracted with water is treated with alcohol containing formic acid, which forms stable salts with narcotine, papaverine, and thebaine; the alcohol and excess of formic acid are removed from the solution and the separated inactive substances added to the aqueous extract; after diluting the mixture with water to precipitate mucilaginous substances, with or without subsequent addition of a lead salt to remove dissolved albuminous substances and subsequent removal of the excess lead, the filtered liquid is evaporated *in vacuo*. The product is suitable for injections, containing all the alkaloids of opium in their natural forms of combination and proportions.

—F. W. A.

XXI.—PHOTOGRAPHIC MATERIALS AND PROCESSES.

X-ray materials; Sensitometry of —. M. B. Hodgson. Communication No. 63 from The Kodak Research Laboratory. Brit. J. Phot., 1917, 64, 654—657.

THE author used a modified form of the exposing apparatus designed by Jones, in which a series of exposures was given by moving the plate across a lead-protected diaphragm; this avoided the difficulty of synchronisation which occurs by reason of the intermittent nature of X-radiation, if the usual revolving sector wheel is employed. A Coolidge tube was used to obtain a steady output of X-rays in a continued exposure, the usual type of tube not being satisfactory in this respect. No unit of radiation is suggested, an arbitrary unit being employed in the curves given. These do not quite resemble those obtained by light exposures, being more hyperbolic in shape and showing no over-exposure period. Curves are given showing the effects of variation in development, exposure, and hardness of tube, and also the effect of using an intensifying screen. The two former are quite in line with light-exposures. With increasing softness of tube, as measured by the equivalent spark-gap, the curve gets steeper and the useful exposure range smaller; an intensifying screen gives greater speed and greater steepness.—B. V. S.

Fixation [photographic]; Laws of —. A. W. Warwick. American Photography, 1917. Brit. J. Phot., Dec. 7, 1917, 617—620.

THE amount of silver salt removed from a film by a bath of sodium thiosulphate was determined by the colour reaction of the solution with sodium sulphide, compared with a solution of known content. Under normal conditions the reaction follows the usual rule, a certain fraction of the remaining silver salt being removed in unit time; with 20% solution at $65^{\circ}F$. ($18^{\circ}C$.) the rate is roughly half the silver in 2 minutes. The total time necessary for efficient fixation is dependent on this factor and on the actual silver content of the film; a convenient guide is the time taken to "clear" the film (remove the opalescence), which is about half that required for complete fixation. The factor depends on the temperature, the character of the silver salt in the film, and the

strength of the fixing bath; the rate rises gradually with increase of strength up to about 40% and then falls away somewhat more quickly, being zero again at saturation, about 63% at 65° F. (18° C.).

—B. V. S.

Iodine and iodine-thiourea as subtractive reducers for photographic negatives and positives. S. Beeher and M. Winterstein. *Z. wiss. Phot.*, 1917, 17, 1—16.

IODINE can be used as a photographic reducer in solution in potassium cyanide, in potassium iodide, or in alcohol and also in combination with thiourea. The solution in cyanide is not satisfactory in use because of the continued action after removal of the image from the reducing bath; treatment with "hypo" stops the action of the iodine but not that of the cyanide, which is still considerable as cyanide itself has a definite reducing action. The other methods of using iodine are free from this defect, "hypo" having an immediate arresting effect on their action; on this account very thorough washing is necessary before treatment with an iodine reducer. Very dilute solutions are recommended:—For plates (a) 1 to 4 c.c. of iodine-potassium iodide solution (1:2:200) in 100 c.c. of water; (b) 2—8 c.c. of the iodine-potassium iodide to 100 c.c. of 4% thiourea solution; for paper, solutions about half the strength of those for plates or a solution of from 4 to 16 c.c. of iodine tincture (1:100 c.c. of 95% alcohol) to 100 c.c. of 50% alcohol. The time necessary for reduction varies from 1 min. to about 6 mins. with the first two baths and up to as long as 10 mins. with the alcohol solution. The potassium iodide and alcohol solutions give a yellowing of the image by the formation of silver iodide but it is quite easy to judge the amount of reduction. A final bath of "hypo" is necessary to dissolve the iodide and to arrest the action of the reducer, for the latter reason also after the thiourea bath. The strength of the thiourea solution must not be appreciably higher than 4%, as although the authors were unable to confirm previous statements that thiourea has itself a reducing action, in stronger solution its destructive action on the gelatin film is quite marked. The reducing action of iodine was compared with that of other reducers; it resembles cyanide and Farmer's ferricyanide-hypo reducer in acting evenly over the whole image, in contrast with permanganate which acts proportionally to the depth of the image and copper chloride and ammonium persulphate which act more strongly on the shadows. The solution in potassium iodide but not the alcohol or thiourea solution gives the usual blue colour with papers containing starch; it disappears, however, immediately in the subsequent "hypo" bath.—B. V. S.

PATENTS.

Photographic negatives; Process for improving —. A. Boularan, dit Devel, Paris. U.S. Pat. 1,245,152, Nov. 6, 1917. Date of appl., Sept. 15, 1916.

A TRANSPARENCY from an intensified negative is coated with coloured bichromated gelatin, dried, and exposed through the back. After development of the resulting negative the silver image (of the positive) is removed by treatment with a bath of potassium ferricyanide and sodium thiosulphate.—B. V. S.

Colour photography. F. E. Ives, Philadelphia, Pa. U.S. Pat. 1,247,116, Nov. 20, 1917. Date of appl., Mar. 12, 1915.

IN making a coloured print from a three-colour

mosaic transparency, three monochrome images in silver are first made, corresponding with the three colours of the transparency. These are then transformed to images in the complementary colours to those of the transparency and the three resulting prints superposed in register. For the blue print, complementary to red, the silver is replaced by Prussian blue in the usual way. The other colours are obtained by bleaching the print in bichromate and bromide, developing in hot water to form colloid relief prints, and then dyeing to the required colour.—B. V. S.

XXIII.—ANALYSIS.

Platinum ware: Some substitutes for —. R. F. Heath. *Met. and Chem. Eng.*, 1917, 17, 666—667.

COMPARATIVE tests were made on crucibles made of platinum, gold, silver, nickel, fused quartz, and an alloy of canadium (see this J., 1912, 29), 1 part, palladium, 1 part, platinum, 2 parts, and nickel, 6 parts. In the first test, heating the weighed crucibles 32 hrs., cooling, and reweighing, platinum gave distinctly the poorest result, losing 0.14% as against the next highest, silver 0.017%. In the tests by immersion in strong acids (hydrochloric, sulphuric, and nitric) platinum gave each time the lowest figure, but gold, canadium alloy, and quartz all gave good results, the highest figures being 0.04% loss for gold in hydrochloric acid, and 0.02% for the canadium alloy in nitric acid; silver gave a better test than gold in hydrochloric acid but a high figure in sulphuric acid, and nickel was not good in either of them. The particular merits and demerits of the various materials as regards their resistance to halogens, alkalis, high temperatures, etc., are also considered. The canadium alloy is a good general substitute for platinum, having similar resisting powers and a melting point of about 1570°C.; its cost is about half that of platinum.—B. V. S.

Fractional distillation under diminished pressure; An efficient apparatus for —. W. A. Noyes and G. S. Skinner. *J. Amer. Chem. Soc.*, 1917, 39, 2718—2720.

A SEPARATING funnel is fused into the side of a Claisen flask, thus permitting the introduction of successive fractions without losing the vacuum, and a simple fractionating column is sealed on to the side tube of the flask.—W. G.

Micro-analysis; Quantitative —. C. Reichard. *Pharm. Zentralh.*, 1917, 58, 493—498, 534—540.

INSTANCES are given of the applicability of micro-analysis, i.e., the determination of very small quantities of constituents when using minimum amounts of material. Provided that accurate measuring vessels and a sensitive balance are employed, it is quite possible to determine accurately the extractives and ash in 5 c.c. of wine, etc.; small capsules formed out of platinum foil are used for the purpose. Micro-analysis is particularly suitable for the determination of phosphorus, since this yields a precipitate of ammonium phosphomolybdate having a weight fifty-five times that of its phosphorus content. In the determination of small quantities of carbon, it is preferable to use a gas-volumetric method, the volume of carbon dioxide produced from the carbon being readily determined; the same applies

to nitrogen, ammonia, and hydrogen. Very small quantities of metal in oxides (e.g., zinc in zinc oxide) may be determined by measuring the volume of hydrogen evolved when the substance is treated with an acid.—W. P. S.

Manganese; Colorimetric determination of—by oxidation with periodate. H. H. Willard and L. H. Greathouse. J. Amer. Chem. Soc., 1917, 39, 2366—2377.

MANGANESE salts are oxidised by periodates according to the equation: $2\text{Mn}(\text{NO}_3)_2 + 5\text{KIO}_4 + 3\text{H}_2\text{O} = 2\text{HMnO}_4 + 5\text{KIO}_3 + 4\text{HNO}_3$, and the amount of permanganate produced may be determined by comparison with a solution of known strength. A slight excess of periodate is necessary to ensure complete oxidation of the manganese salt, but the only effect of increasing the excess is the acceleration of the reaction. A minimum excess of acid is also necessary to complete the reaction and to avoid precipitation; the minimum increases with increase of the amount of manganese and varies with different acids, being lowest with phosphoric acid. Heating is necessary, boiling for 10—15 mins. being the usual method. If chlorides are present they are decomposed, and the chlorine driven off by boiling. Ammonium salts do not interfere with the reaction. The amount of manganese present has no effect except that with large amounts the colour is too strong for accurate matching. Reducing substances such as ferrous salts must first be oxidised with nitric acid to prevent the formation of iodine. If ferric salts are present their disturbing effect on the colour may be counteracted by the addition of an equal amount to the standard solution. The colour is very permanent in presence of an excess of the periodate. The method is applicable to the analysis of iron and steel, of which several examples are given. A comparison is also given with the persulphate oxidation of manganese and a bibliography of the subject.—B. V. S.

Cupferron (phenyl-nitrosohydroxylamine-ammonium); Use of— in: I. Quantitative separation of zirconium, titanium, iron, manganese, and aluminium. II. Analysis of zircon and baddeleyite. J. Brown. J. Amer. Chem. Soc., 1917, 39, 2358—2366.

IN the analysis of mixtures of salts of iron, zirconium, titanium, aluminium, and manganese, cupferron in acid solution was used for the separation of the first three elements. The metals were brought into solution in sulphuric acid, an excess of about 12½% of acid being present. The cupferron precipitate, after thorough washing, was ignited to remove the excess of cupferron, the resulting oxides fused with bisulphate and dissolved in dilute sulphuric acid. The iron was separated as sulphide in the presence of tartrate. Three methods were used for the determination of the zirconium in the residual filtrate, after oxidation of the tartaric acid. When large amounts of titanium were present, the zirconium and titanium were precipitated together as hydroxides and weighed as oxides, and then either the titanium determined by reduction with sulphur dioxide and titration with permanganate and the zirconium determined by difference, or the zirconium separated as phosphate, the operation being repeated to remove the last traces of titanium. When smaller amounts of titanium were present, Weller's colorimetric method with hydrogen peroxide was used for the determination of titanium, and the zirconium was determined as

phosphate. The separation of the aluminium and magnesium was made by standard methods. In the analysis of zircon, which contains no manganese, a preliminary treatment for the removal and estimation of silica was necessary; in the analysis of baddeleyite, which contains manganese, water as well as silica had to be determined.—B. PATENT.

Gases; Method of and apparatus for testing [calorific value of]— G. G. Crewson, Tottenville, N.Y., Assignor to The Roessler and Hasslacher Chemical Co., New York. U.S. Pat. 1,245,688, Nov. 6, 1917. Date of appl., July 3, 1916.

To determine the calorific value of gas the latter is pumped from a container to a burner placed below a metal coil through which a current of water is passed. The supply of water is regulated and actuated by the gas pump, and the temperature of the water is read before and after it has passed through the coil.—W. P. S.

Patent List.

The dates given in this list are in the case of Applications for Patents, those of application, and in the case of Complete Specifications accepted, those of the Official Journals in which the acceptance is announced. Complete Specifications thus advertised as accepted are open to inspection at the Patent Office immediately, and to opposition within two months of the date given.

I.—GENERAL; PLANT; MACHINERY.

APPLICATIONS.

Avery. Drying-apparatus. 22. Jan. 2.

Brand. Channel furnaces. 116. Jan. 2.

Breakell. Means for covering in and discharging grinding, crushing, and mixing mills. 227. Jan. 4.

British Carbonizing Co., and Garbutt. Rotary furnaces. 246. Jan. 4.

Bynoe. Drying and/or heating air. 462. Jan. 8.

Chemical Engineering and Wilton's Patent Furnace Co., Hinds, and Stinchcombe. Furnaces. 530. Jan. 9.

Faïencerie de Gien. 443. *See under VII.*

I.—GENERAL; PLANT; MACHINERY.

Gas-fired boilers. T. M. Hunter. Inst. Elect. Engineers. [Advance proof.] 18 pages.

THE author referred to the difficulties that had been experienced in firing boilers economically with gas, due chiefly to unsatisfactory arrangements for burning the gas. The three chief classes of gas used are:—coke-oven gas, blast-furnace gas, and producer gas. Coke-oven gas has a high calorific value and is fairly clean, but blast-furnace gas carries a great deal of dust and should be passed through a gas-cleaning plant before use. From the point of view of efficiency it is more important that a gas should be dry than free from dust, especially if used with water-tube boilers. The presence of water in the gas causes: (1) a lower efficiency, (2) less evaporation, and (3) a considerable loss due to lowering of flame temperature. As with coal-fired boilers, it is important to have the boilers covered and the settings air tight, as the introduction of "false air" causes most serious losses. Painting the settings with several thick coats of tar is advocated, and either induced draught or automatic dampers are advised when using gas. In addition to draught control it is important to have the gas at a constant pressure or to use a type of burner that is not affected by the gas pressure. To obtain the best results the gas and the water should be measured, the waste gases should be analysed, and the temperature in the flues should be recorded. The author gives a number of useful tables in an appendix.—W. H. C.

Action of caustic soda on steel plates. Stromeayer. See X.

PATENTS.

Ether and alcohol vapour contained in the air of factories; Process and apparatus for recovering the —. E. Barbet et Fils et Cie., Paris. Eng. Pat. 101,723, Oct. 6, 1916. (Appl. No. 14,235 of 1916.) Under Int. Conv., Oct. 7, 1915.

THE air containing the ether and alcohol vapours is passed up a plate column of acid-proof material down which relatively dilute sulphuric acid flows. The vapours are absorbed by the acid which is then, without further dilution, passed down a column still, and the ether, alcohol, and part of the water are distilled off, cooled, and condensed in suitable vessels. The acid is returned to the absorbing column for use over again. By regulating the temperature of distillation, the dilution of the residual acid may be varied so that any desired proportion between the alcohol and ether absorbed may be maintained.—W. H. C.

Ether and alcohol vapours contained in the air of factories; Apparatus for recovering —. E. Barbet et Fils et Cie., Paris. Eng. Pat. 101,875, Oct. 12, 1916. (Appl. No. 14,531 of 1916.) Under Int. Conv., Oct. 16, 1915. Addition to Eng. Pat. 101,723 (see preceding abstract).

To overcome the difficulties caused by the variation in the amount of ether and alcohol vapours which occurs in the air to be treated, a valve, operated by a densimeter or float placed in an extension of the air main and which rises or falls as the percentage of vapours passing to the recovery apparatus varies, is placed in the inlet main to the recovery apparatus described in the principal patent.—W. H. C.

Waterproofing and rendering impervious to dust bags and sacks; Method of —. J. Gadsen, Melbourne, Australia. Eng. Pat. 109,252, July 25, 1917. (Appl. No. 10,676 of 1917.) Under Int. Conv., Aug. 28, 1916.

BEFORE filling, the interior of the bag is sprayed or coated with a suitable adhesive fluid and the bag is at once filled. A thin layer of the material packed in the bag adheres to the fluid and forms an impervious layer which protects the rest of the contents.—W. H. C.

Gas filling apparatus. The New Jersey Zinc Co., New York, Assignees of G. S. Brooks and L. G. Duncan, De Pue, Ill., U.S.A. Eng. Pat. 110,907, Mar. 9, 1917. (Appl. No. 11,048 of 1917.) Under Int. Conv., Nov. 1, 1916. (See also U.S. Pat. 1,240,305 of 1917; this J., 1917, 1171.)

THE dust-laden gases pass through a flue into a bag chamber, the gases being driven forward by a fan placed in the flue. A by-pass is provided to connect the outlet of the bags with the inlet of the fan, and valves controlled by rods are provided on the inlet flue for the gases and on the by-pass flue. The valves are connected with bag-shaking mechanism, which is operated intermittently by electrical means, the arrangement being such that when the bag-shaking device is operated, the bag outlets are put into connection with the fan inlet and the supply of dust-laden gas to the bag is shut off, so that whilst the bag is being shaken a current of air is drawn through and clears the interstices of the filter from solid particles.—W. H. C.

Cleansing or washing smoke, air and other gases, and extracting soot, dust, and other impurities therefrom; Apparatus for — or for evaporating liquids. A. Hindmarsh, Newcastle-on-Tyne. Eng. Pat. 111,637, May 21, 1917. (Appl. No. 7339 of 1917.)

THE air or gas is passed through a horizontal cylinder within which a perforated drum is rotated upon a hollow shaft provided with blades. Water or other suitable liquid is fed into the hollow shaft and also independently into the outer cylinder. The perforated drum is provided with external fan blades which dip into the liquid in the bottom of the cylinder as they rotate.—W. H. C.

Heating and cooling apparatus and the like. S. S. Guy, Wolverhampton. Eng. Pat. 111,556, Dec. 13, 1916. (Appl. No. 17,879 of 1916.)

IN cooling or heating apparatus consisting of several cylinders enclosed in a common jacket through which the heating or cooling medium is passed, hollow partitions of wedge-shape or V-shape in cross section, made of thin metal, are interposed between the cylinders. In this way the surging of the liquid cooling or heating medium in the jacket is prevented, and the liquid is brought into more intimate contact with the walls of the cylinders.—W. H. C.

Separating substances of different specific gravities, such as fine coal or ores and the like; Apparatus for —. J. M. Draper, Bridgend, and The Rhondda Engineering and Mining Co., Ltd., Cardiff. Eng. Pat. 111,826, Oct. 5, 1917. (Appl. No. 14,404 of 1911.)

THE material is fed into a conical perforated funnel placed in the upper part of a vertical vessel up which a current of water flows, and carries the finer particles to the overflow. A slowly-rotating valve is provided at the lower end for the discharge of the heavier particles. A balancing liquid column is provided, contained in a vertical pipe.

the lower part of which is attached to the separating chamber at a point between the overflow and bottom discharge. The upper part of the pipe contains air to form an air cushion and has a valve to allow of the escape of air during filling.—W. H. C.

Drying apparatus. H. G. C. Fairweather, London. From Pacific Evaporator Co., Portland, Oreg.. U.S.A. Eng. Pat. 111,994, Sept. 5, 1917. (Appl. No. 12,735 of 1917.)

THE materials to be dried are supported on trays having perforated bottoms and placed in tiers on trucks so that the trays are slightly inclined to the horizontal; the trays on alternate rows of trucks are inclined in opposite directions. The trucks are moved on rails along the drying chamber across which heated air or other drying medium is passed. As the drying progresses the trucks with the trays are moved towards the air inlet end of the apparatus. To effect economy, primary and secondary drying chambers are used, the air passing first through the secondary chamber over the nearly dry material and then through the primary chamber over the fresh material.—W. H. C.

Dryer. W. D. Palen, Philadelphia. Assignor to The Philadelphia Textile Machinery Co. U.S. Pat. 1,248,389, Nov. 27, 1917. Date of appl. May 3, 1916.

A DRYING chamber is provided with two platforms, one above the other, the lower one extending beyond the upper. A flight conveyor travels on the platforms. A rotary distributor having blades located below and beyond the discharge end of the upper platform and clear of the conveyor is arranged so that material which accumulates in front of the flights of the conveyor on the upper platform will be discharged on to the distributor and will fall from this on to the lower platform.—J. H. P.

Dryer and evaporator. C. Offenhauser, Philadelphia, Pa. U.S. Pat. 1,249,177, Dec. 4, 1917. Date of appl., July 9, 1917.

THE material to be dried is passed through the annular space between two co-axial drums. The inner drum is stationary and is heated internally, and the outer drum is rotated. The outer drum is provided with scrapers on the inside which remove the material from the outer surface of the inner drum.—W. H. C.

Centrifugal separator. J. H. Blair, Assignor to R. H. Taylor, jun., Philadelphia, Pa. U.S. Pat. 1,246,035, Nov. 13, 1917. Date of appl., Sept. 21, 1915.

A ROTARY dryer comprises a sectional tub having its parts mounted to separate outward and a confining member, movable axially with respect to the tub, to hold the parts in assembled position.—J. H. P.

Centrifugal machine. E. R. Curtis, Brighton. U.S. Pat. 1,248,821, Dec. 4, 1917. Date of appl., June 4, 1917.

A CYLINDRICAL vessel is provided with an axial inlet in the cover for liquid to be treated, and an axial outlet in the bottom which has a deep upward indentation. A hood is fitted over the indentation and radial ribs are provided in the enclosed space to provide passages for the liquid. A series of concentric corrugated cylindrical surfaces are provided near the cylindrical wall of the casing, supported alternately from the cover and the bottom, and a number of sector-shaped troughs are arranged in the bottom of the vessel and maintained in position by projections on the hood. The liquid passes first into the central space of the vessel, over the trays, and then in a zig-zag path

over the corrugated surfaces to the space between the hood and the bottom, and thence to the central outlet in the bottom.—W. F. F.

Vapour-condensing apparatus. J. E. Phillips. Sherman, Tex. U.S. Pat. 1,246,154, Nov. 13, 1917. Date of appl., June 6, 1916.

A CONDENSER is connected with a preliminary cooling and mixing chamber having a series of annular baffles surrounding a central space and occupying a part of the height of the chamber. The vapour is supplied to the space above the baffles and a pipe supplies liquid which is mixed with the vapour in this space. The mixed liquid and vapour are conveyed from the space below the baffles to the condenser.—J. H. P.

Filtering machine; Automatic, continuous centrifugal—H. A. Herr, Philadelphia, Pa. U.S. Pat. 1,246,267, Nov. 13, 1917. Date of appl., Oct. 19, 1914.

THE shaft which carries the basket of the machine is so supported that the basket may be rotated eccentrically at a high speed. When the basket is full, the speed is checked and the eccentricity is arrested, and the basket is emptied while running at a low rate of speed.—W. H. C.

Separator for pulverising-mills; Pneumatic—E. J. Steckle, Dixon, Ill. U.S. Pat. 1,246,344, Nov. 13, 1917. Date of appl., Jan. 31, 1916.

THE pulverised material is delivered through a number of nozzles which project upward from the grinding chamber into a separating chamber above. The nozzles pass through the bottom of the separating chamber tangentially and the more finely powdered material is drawn off from the separating chamber by a current of air. The coarser particles fall to the bottom and are returned to the grinding chamber.—W. H. C.

Pulverising and treating ores, clay, and other mineral substances; Process of and apparatus for—A. B. Willoughby, Philadelphia, Pa. U.S. Pat. 1,246,514, Nov. 13, 1917. Date of appl., May 6, 1914.

THE material to be pulverised is delivered to a heated platform to be dried, and then passes downward through two shoots to a pair of nozzles directed towards one another. Superheated steam at high temperature and pressure is also supplied to the nozzles so that the two streams of material impinge against one another at high velocity. The pulverised material and steam are withdrawn through an exhaust flue into which fresh superheated steam at high pressure and temperature is also supplied to reheat the cooled steam and to separate the lighter particles of the pulverised material. The steam is passed into a settling chamber, where the pulverised material separates, and the steam is discharged while still dry. The heavier unpulverised material is returned to the top of the shoot. The drying platform is heated by waste gas from the boiler which supplies the steam.—W. F. F.

Spraying liquids and treating gases; Process and apparatus for—C. C. Thomas, Baltimore, Md. U.S. Pat. 1,246,355, Nov. 13, 1917. Date of appl., May 3, 1915.

THE apparatus comprises a spray head in the form of a vertical tube of resilient material having in its periphery a helical slot with abrupt discharge edges. This slot varies in inclination from one end to the other, whereby the liquid can be discharged in the form of a helical film varying in direction from one end to the other of the spray head. For treating gases the spray head is fitted inside a chamber provided with a gas inlet and outlet. The liquid is ejected into the current of gas in the

form of a thin helical film at an angle to the direction of the flow of gas, and the pressure of the liquid and width of the slot can be regulated to cause the film to be broken up and atomised in contact with the gas.—J. H. P.

Solidified plastic articles; Apparatus for rapidly ageing —. De N. W. B. Young, Narberth, Pa., Assignor to Soap Works Equipment Co. U.S. Pat. 1,246,515, Nov. 13, 1917. Date of appl., Jan. 10, 1916.

AN endless conveyor carrying a series of free swinging holders passes in a zig-zag path through a chamber containing hot air at constant temperature, and then through a cooling chamber. Solidified plastic articles are fed into the hot compartment in the path of the holders, and means are provided in the cooling chamber to tilt the holders and discharge the articles. The air in the hot compartment is heated by pipe coils between the adjacent runs of the conveyor.—W. F. F.

Fire extinguisher compositions. H. S. Mork, Brookline, Mass., Assignor to American La France Fire Engine Co., Elmira, N.Y. U.S. Pats. (A) 1,246,640, (B) 1,246,641, and (C) 1,246,642, Nov. 13, 1917. Dates of appl., Feb. 26, Mar. 27, and Mar. 27, 1917.

(A) THE composition consists of carbon tetrachloride, a component to lower the freezing point, e.g., chloroform, and an aromatic ester. A typical composition is 95 c.c. of carbon tetrachloride, 5 c.c. of chloroform, and "2.5 grms. of triphenyl phosphate and phenyl salicylate in equal parts." (B) A mixture of 92½% of carbon tetrachloride, 2½% of chloroform, and 5% of "safrol." (C) A mixture of 90% of carbon tetrachloride, 5% of chloroform, and 5% of pine oil.—J. H. P.

Evaporator. W. H. C. Smith, Philadelphia, Pa. U.S. Pat. 1,246,824, Nov. 13, 1917. Date of appl., Apr. 23, 1917.

A VERTICAL cylindrical casing has its base dished inwards, and a tubular heating drum with vertical tubes is provided in its lower portion so that the lower tube-plate is approximately parallel to the base of the casing and forms with it a circular chamber having a number of circumferential openings into the casing. A liquid-supply pipe enters this chamber and the liquid circulates through the tubes. Steam is supplied through a vertical pipe passing axially downward through the casing and terminating in a nozzle of smaller section in the centre of the heating drum and near the bottom of the casing. The connection between the steam pipe and the top of the drum is made flexible to permit relative movement.—W. F. F.

Evaporating or concentrating process. F. P. Bergh, Yonkers, N.Y., Assignor to Central Reduction Co. U.S. Pat. 1,249,001, Dec. 4, 1917. Date of appl., Jan. 10, 1912. Renewed Feb. 23, 1917.

THE liquid to be evaporated is introduced as a stratum of spray into the middle portion of the evaporating chamber, and a current of dehydrating air or gas is introduced into the chamber below the stratum of liquid. The gas passes upwards through the liquid and evaporates the latter, and the vapour-laden air or gas and the finely-divided solid pass upwards through a screen which separates the solids.—W. H. C.

Gases; Apparatus for separating mechanical mixtures of —. J. O. Carrey, Assignor to Carrey Process Co., St. Louis, Mo. U.S. Pat. 1,248,454, Dec. 4, 1917. Date of appl., Apr. 10, 1915.

THE mixed gases are admitted to a receiving chamber mounted in a vertical frame which supports also a vertical rotating shaft carrying a

separating drum connected with the receiving chamber. A number of outlet passages from the rotating drum are provided at different radii and exhausting devices are provided in the passages to withdraw the separated gases from the drum.

—W. F. F.

Carboys, kegs, or the like; A two-wheeled, hand-propelled vehicle to carry two —. British Dyes, Ltd., J. Turner, and W. Hindle, Huddersfield. Eng. Pat. 111,927, Dec. 27, 1916. (Appl. No. 18,443 of 1916.)

IIa.—FUEL; GAS; MINERAL OILS AND WAXES.

Coal; Spontaneous heating of —. G. Knox, Gas J., 1918, 141, 110—111.

MICROSCOPICAL and chemical analysis shows that coals are composed chiefly of humus bodies (high oxygen content with much hygroscopic water), resinous bodies (medium oxygen content, melting at 300° C.), and carbon, with a varying percentage of hydrocarbon, moisture, and mineral matter. Coal has the power of absorbing gases, in some cases to the extent of three times its own volume; the absorbed gas is very active chemically, and the chemical action (oxidation) increases the temperature of the coal. Coal being an excellent non-conductor, the heat generated increases steadily and with increasing rapidity until the ignition point of the coal is reached. This point is generally stated as varying between 370° C. for cannel and 477° C. for Welsh steam coal, but it varies according to the state of division of the coal. Spontaneous heating is more common in coals of high volatile content and has been a source of trouble in shipping. The length of the journey has been the determining factor in a number of cases of spontaneous ignition, showing that a certain time limit is necessary to enable the oxidation to generate sufficient heat. Cases of heating in coal stored on the surface are common, and coking coals stored for long periods lose their coking properties. The author gives the following hints as to the prevention of heating. Wherever possible the coal should be sized before stacking, and each size put in a separate heap. "Through" coal or mixed small coals should never be stacked to a height of more than 13 feet. If it is necessary, on account of lack of space, to store to a greater height than this, the coal should be laid down in successive layers of not more than 3 to 4 feet thick. An iron or earthenware ventilation pipe, 3 to 4 ins. in diameter, should be inserted for every 300 sq. ft. of surface. A thermometer should be lowered occasionally to ascertain the temperature at various depths. Coal should never be stacked in contact with wood, moist vegetable soils, or coarse vegetation like bracken. Dirty coals should not be mixed with the better class varieties, and as far as possible all "rashings" or other friable bituminous shale bands should be removed before storing. Coking coals should not be stored in heaps of more than 4 ft. and only for short periods, as very slight heating renders them useless for coking purposes. Wet coal should not be mixed with dry coal, but should be dumped round the edges of the stack with free access to the air.

—J. E. C.

Naphthalene; Use of crude — as fuel for internal combustion engines. J. H. Willis. Gas J. 1918, 141, 65—67.

THE author describes a method of utilising crude naphthalene in an internal combustion engine of about 10 B.H.P. installed in a motor launch. In the vaporiser used (designed by the author and G. G. Wilson) the molten naphthalene does not pass through any pipes of small diameter or through a spray. This vaporiser is of the "surface" type and is self-contained, acting also as the fuel storage vessel. It consists of a rectangular exhaust jacketed vessel, built up of thin steel plate, all joints being oxy-acetylene welded. The apparatus is bolted to the top of an exhaust jacketed T-piece, the ordinary petrol carburettor being fitted to the bottom. The back pressure of the silencer is sufficient to force some of the exhaust gases round the vaporiser. The portion of the air which it is proposed to carburet approximately to saturation is drawn by the suction of the engine through the molten naphthalene, the secondary air being drawn through the petrol carburettor, the jet of which is closed. The naphthalene used in the experiments was crude, but of fairly good quality, extracted from coal-gas during the process of benzol and toluol recovery. The engine was run for five or ten minutes on petrol and when the naphthalene had reached a temperature of about 130° C. the petrol was turned off completely. It was found that satisfactory running could be obtained by passing one-thirteenth of the air through the carburettor. Little difficulty was experienced with the carburation even with temperatures varying between 130° and 160° C. The calorific value of naphthalene is 17,395 B.Th.U. per lb. as compared with 20,100 and 18,700 for paraffin and petrol respectively.—J. E. C.

Briquettes or other moulded articles; Process of making —. Briquetting process. Weather-resistant briquette. C. Ellis, Montclair, N.J., Assignor to Ellis-Foster Co., N.J. U.S. Pat. 1,246,805, 1,246,807, and 1,246,808, Nov. 13, 1917. Dates of appl., (A) Mar. 28, 1913, (B) May 2, 1917, (C) July 5, 1917.

(A) BRIQUETTES, or other moulded articles are made by mixing concentrated acid sulphite-cellulose waste liquor with a bulking material containing coal dust and coal fragments, and quick-lime is incorporated in order to precipitate the solids from the liquor. (B) Acid sulphite-cellulose waste liquor is atomised, and the finely divided solids which are obtained, are dissolved in water to form a binding agent. This is mixed with the bulking material, moulded under pressure, and the material is treated to render the dissolved solids insoluble, and then allowed to set to form a weather-resistant briquette. (C) Sulphite-cellulose waste liquor is incorporated with a bulking agent, and a basic compound of magnesium, such as the oxide, is used as precipitant, the mass being afterwards pressed into the required shape.—B. N.

Fuel and process of burning the same. C. F. Schrimpe, Perth Amboy, N.J., Assignor to The Perth Amboy Chemical Works, New York. U.S. Pat. 1,248,557, Dec. 4, 1917. Date of appl., Apr. 28, 1916.

A FUEL contains approximately 100 parts by

weight of hexamethylenetetramine, 20 parts of a substance yielding oxygen slowly to the hexamethylenetetramine, such as potassium permanganate, and 20 parts of solid paraffin.—J. E. C.

Coke ovens; Regenerative —. D. Bagley, London. Eng. Pat. 111,801, May 18, 1917. (Appl. No. 7138 of 1917.)

ONE regenerative chamber is placed above and one below a coke oven heated by vertical flues. The regenerators are in the same plane as, and extend the full length of, the coking chamber. They are used alternately according as the direction of the flame in the heating flues is upward or downward. In the first case hot air from the lower regenerator meets the gas at the base of the flues, and the products of combustion ascend through the vertical flues and passing through the upper regenerator give up their residual heat to the chequered brickwork. At certain periods this sequence is reversed, the upper regenerators supplying the hot air and the direction of the heating flames being downward. The upper and lower regions of the oven walls are thus more evenly heated.—J. E. C.

Furnace and oven apparatus; Operating — with recovery of heat. H. Koppers, Essen-on-the-Ruhr, Germany. Assignor to H. Koppers Co. U.S. Pat. 1,246,114, Nov. 13, 1917. Date of appl., July 27, 1914.

IN operating a regenerative furnace heated by producer gas, the reversal is effected by interrupting the air and steam supply to the producer to stop the gas production therein, cutting the furnace off from the producer, changing the position of the air and waste heat valves of the furnace, and re-connecting the furnace, the air, and the steam supply to the producer.—J. E. C.

Coke-producing and by-product-recovery method. M. Marshall, sen., Port Coquitlam, British Columbia. U.S. Pat. 1,248,883, Dec. 4, 1917. Date of appl., Aug. 14, 1917.

THE heat from the upper strata of a charge of coal is drawn downwards by an induced draught through the remainder of the charge. The volatile constituents are thus extracted, pass downwards in separate streams, and then through finely-divided material to the condensers.—J. E. C.

Fuel[gas]; Manufacture, utilisation, and combustion of —. G. Helps, Nuneaton. Eng. Pat. 111,495, Aug. 24, 1916. (Appl. No. 12,011 of 1916.)

A HYDROCARBON gas, e.g., coal gas, is mixed with pure blue water-gas, the mixture having a net calorific value of from 335 to 250 B.Th.U. per cubic foot, or other diluents (Mond gas, producer gas, air, or nitrogen) may be used, in which case the calorific value of the mixed gases may be from 400 to 250 B.Th.U. per cubic foot. These mixtures may be used at low pressures so as to give coneless flames in close contact with the object to be heated. The mixture of coal gas and diluting gas may be made during the process of manufacture as described in Eng. Pat. 14,750 of 1916, or the gases may be mixed subsequently.—J. E. C.

Carburetted water-gas; Production of —. G. E. Heyl, London. Eng. Pat. 111,934, Jan. 5, 1917. (Appl. No. 252 of 1917.)

SULPHUR-CONTAINING oils are vaporised and the vapours carried by a stream of water-gas to a superheating chamber in which the vapours are cracked. The mixed gases and vapours then pass through a purifier containing ferric oxide or other sulphur-removing substances.—J. E. C.

Gas producers. T. R. Wollaston, Manchester. Eng. Pat. 111,964, Mar. 19, 1917. (Appl. No. 3963 of 1917.)

WATER or tar or both may be admitted in a finely divided or atomised condition into the interior of a fixed hollow core or dome extending upwards from the grate of a gas producer, and the products are thereby vaporised and superheated prior to being introduced into the combustion zone.

Coke-oven and gas works; Treatment of refuse from —. S. N. Wellington, London, and S. B. Etherton, Barnsley. Eng. Pat. 111,883, Dec. 8, 1916. (Appl. No. 17,698 of 1916.)

REFUSE liquors, such as "devil" or waste liquors from coke-oven or gas works, are admitted, with or without the addition of lime, into gas producers, for total destruction of the noxious constituents.

—J. E. C.

Liquid fuel suitable for use in internal combustion engines; Production of —. J. M. O'Brien, Streatham. Eng. Pat. 111,864, Sept. 5, 1916. (Appl. No. 12,579 of 1916.)

ORDINARY commercial paraffin is agitated with strong sulphuric acid, bleaching powder, and petroleum ether. The filtered material may be mixed with petrol in various proportions, and if desired may be treated with silicic acid in an absorbent form.—J. E. C.

Liquid hydrocarbons [; Production of light] —. G. E. Heyl, London. Eng. Pat. 111,933, Jan. 5, 1917. (Appl. No. 251 of 1917.)

THE yield of lighter liquid hydrocarbons in fractionally distilling heavier hydrocarbons (mineral oils, coal oils, coal-tar oils, shale oils, and the like) is increased by impregnating the oil, before distillation, with a hydrocarbon gas or with hydrogen, without external heating. By preventing an increase in temperature during absorption, or, preferably, by reducing the temperature of the hydrocarbon, during absorption, below the prevailing temperature, the yield is still further increased.—L. A. C.

Crude petroleum and the distillates thereof; Apparatus for treating —. C. B. Forward, Urbana, Ohio. U.S. Pat. 1,247,808, Nov. 27, 1917. Date of appl., Sept. 15, 1915.

A SET of condensers, each with a separate outlet at the bottom, is arranged in series, the top of one condenser being connected with the bottom of the next. Superheated steam is blown into the bottom of "one of the middle of the series of condensers."—L. A. C.

Heavier hydrocarbons; Method of treating —. S. Schwartz, Assignor to Jenkins Petroleum Process Co., Milwaukee, Wis. U.S. Pat. 1,247,883, Nov. 27, 1917. Date of appl., May 10, 1917.

HEAVY hydrocarbons are heated under pressure in a horizontal cylindrical still and the vapours withdrawn through an artificially cooled collecting device situated within the still between the ends and at the level above the surface of the liquid most suitable for the complete removal of the condensable vapours.—L. A. C.

Liquid fuel for internal-combustion engines. J. P. Foster, Paia, Hawaii. U.S. Pat. 1,248,302, Nov. 27, 1917. Date of appl., Aug. 16, 1917.

A LIQUID fuel comprises a mixture of 2 galls. of methyl alcohol, 100 galls. of ethyl alcohol, 0.5 gall. of pyridine, and substantially 15 galls. of sulphuric ether.—J. E. C.

Gasoline-renovator; Vacuum —. *Process of purifying fluids [gasoline, etc.]*. J. J. Tokheim, Cedar Rapids, Iowa. U.S. Pats. (A) 1,248,950 and (B) 1,248,951, Dec. 4, 1917. Date of appl., Mar. 30, 1916.

(A) THE liquid is fed from a supply tank to a distillation tank through a valve controlled by a float operated from the latter tank. Conduits lead from the distillation tank, into which a steam pipe enters, to a receiver located below it, and to a separator. The conduit to the latter passes through a condenser and has a cold water supply opening into it between the tank and the condenser. (B) A process for purifying gasoline and similar hydrocarbon cleaning liquids, consists in accumulating two bodies of the impure liquid, introducing steam into one body, condensing the vapour, and "effecting an interchange between the water of condensation and the other body of liquid."—L. A. C.

Oil and gas; [from oil-bearing strata] Apparatus for and method of recovering —. F. Squires, Marietta, Ohio, Assignor to W. Squires, Zanesville, Ohio. U.S. Pat. 1,249,232, Dec. 4, 1917. Date of appl., June 19, 1917.

A HEATED, deoxidised gas (products of combustion) is introduced under pressure through a pressure well into an oil-bearing stratum to mix with the hydrocarbon vapour. The mixture is collected from an adjacent venting well, the hydrocarbon (gasoline) recovered by compression and absorption, and the residual products of combustion used again.—L. A. C.

[Petroleum] oils; Treating —. C. Ellis, Montclair, N.J., Assignor to Ellis-Foster Co. U.S. Pat. 1,249,278, Dec. 4, 1917. Date of appl., Apr. 29, 1913.

THE vapours of an oil consisting essentially of petroleum products heavier than gasoline are subjected first to an increasing temperature at or above that of decomposition; then (in the presence of a catalyst) to a decreasing temperature until equilibrium is established. The products are condensed and the portion heavier than gasoline treated again.—L. A. C.

Distillation of heavy oils, oil residues, and bitumens [to produce lighter oils]. W. A. Hall, New York. U.S. Pat. 1,247,671, Nov. 27, 1917. Date of appl., May 3, 1916.

Apparatus for distillation and dehydration of coal tar, mineral or vegetable oils and the like, and debenzolising of wash and other oils and liquids. Eng. Pat. 111,956. See 111.

IIb.—DESTRUCTIVE DISTILLATION; HEATING; LIGHTING.

Cellulose and starch; Distillation of — in *vacuo*. A. Pictet and J. Sarasin. *Comptes rend.*, 1918, 166, 38—39.

PURE cotton cellulose was heated gradually in a distillation apparatus under a pressure of 12—15 mm. After the aqueous fractions there came

over between 200° and 300 C. a thick yellow oil which on cooling solidified to a semi-crystalline mass amounting to 45% of the original cellulose; 10% of carbon remained in the retort. The pasty mass, on recrystallisation from hot acetone or water, gave white tabular anhydrous crystals melting at 179.5° C. Analysis and molecular weight determinations indicated the formula, $C_{11}H_{10}O_5$. The substance was strongly laevo-rotatory and could not be distilled under atmospheric pressure without decomposition; it gave a triacetate, m. pt. 110° C., and a tribenzoate m. pt. 199.5° C. This substance appears to be identical with laevoglucosan obtained by Tanret (Bull. Soc. Chim., 1894, 11, 949) by the splitting of the glucosides picein, salicin, and coniferin. Exactly similar results were obtained by the distillation of starch and apparently also of dextrin. It is suggested, therefore, that laevoglucosan may stand in a direct relationship to the carbohydrates, possibly as a product of simple depolymerisation, and a study of its constitution and the mechanism of its formation may throw some light on the nature of the polymerised carbohydrates.—J. F. B.

PATENTS.

Bituminous shales and the like: Treatment of — for the obtaining of oil therefrom, and apparatus to be used therein. D. and A. Simpson, London. Eng. Pat. 111,605, Mar. 8, 1917. (Appl. No. 3449 of 1917.)

BITUMINOUS shale is subjected to downward distillation, at such a restricted temperature as to liberate the volatile products only, without breaking up the "combinations of so-called fixed carbon." The volatile products pass directly to a desulphurising chamber, whilst the spent shale may be treated in a separate generator for the production of fuel gas and ammonia.—J. E. C.

Carbon [charcoal] and method of producing the same. R. A. Demme, New York. U.S. Pat. 1,249,041, Dec. 4, 1917. Date of appl., Aug. 29, 1917.

HYDROLYSED cellulose material such as wood waste, freed from soluble constituents, is gradually heated to carbonising temperature. Suitable inorganic substances or other carbonisable organic substances may be mixed with the cellulose before heating.—B. V. S.

Enclosed-arc device. J. H. Clough, Schenectady, N.Y., Assignor to General Electric Co. U.S. Pat. 1,246,054, Nov. 13, 1917. Date of appl., Oct. 30, 1915.

A CATHODE of highly refractory material, e.g., tungsten, proportioned to operate at incandescence, and an anode of a chemically active metal, such as calcium, magnesium, titanium or the like, are contained in a sealed envelope filled with argon at a pressure of 5–12 cm. of mercury.—L. A. C.

Retort [for destructive distillation of coal]. H. P. Bostaph, and Bostaph Engineering Co., Detroit, Mich., U.S.A. Eng. Pat. 111,871, Oct. 30, 1916. (Appl. No. 15,477 of 1916.)

III.—TAR AND TAR PRODUCTS.

Benzol recovery plant operation: Laboratory methods for —. F. W. Sperr, jun. Met. and Chem. Eng., 1917, 17, 642–647. (See this J., 1918, 2 A, 26 A.)

THE specific gravity of crude benzol and other light oils is determined with the Westphal balance at 15.5° C., after previously cooling the sample to

12° C. For the sulphuric acid colour test on benzols, toluols, and naphthas, the standard method given in the American Gas Chemists' Handbook is used, the colour being compared with a scale of coloured solutions prepared from cobalt and ferric chlorides and potassium bichromate respectively. The presence of sulphur dioxide and trioxide in washed benzols is detected by exposing methyl orange test paper to the vapours of the benzol issuing from the mouth of the containing bottle. Unsaturated compounds are determined by the method of Kraemer and Spilker (Muspatt's Encyclopaedia, Ger. Ed., 1905, Vol. 8, p. 33), viz., titration with a bromide-bromate of potassium solution in presence of sulphuric acid until the red colour of the bromine persists in the oil. The purity of benzene may be controlled by a determination of freezing point. Carbon bisulphide is estimated by the xanthate method. Hydrogen sulphide may be estimated by washing the sample with sodium hydroxide solution and titrating the extract with iodine after acidification. A specification and tests for wash oil—a "straw" petroleum oil—are given. Benzolised and debenzolised oils are tested by a preliminary distillation in steam, followed by a fractionation of the dried distillate up to 200° C. Naphthalene in oils is estimated by a method based on its volatilisation in a current of warm air. Air at the rate of 1½ cub. ft. per hour is blown through the oil contained in an 8 in. × 1 in. test-tube placed in a bath of water which is heated slowly until boiling and kept at that temperature for 1 hour. The heat is withdrawn and the air bubbled through overnight. The test-tube is fitted with a reflux condenser to condense and retain oils, while the vapours pass on to a train of wash-bottles. The first contains 200 c.c. of N/1 sulphuric acid to retain tar and alkali; then follows an empty bottle to serve as trap and afterwards three bottles each containing 150 c.c. of saturated picric acid solution. Naphthalene picrate is formed and estimated by volumetric determination of the total and free picric acid present.—H. J. H.

Benzols, etc.: Analysis of crude —. W. G. Adam. Gas J., 1918, 141, 65.

THE author gives details of the method used by the Gas Light and Coke Co., for the evaluation of crude benzol. A preliminary distillation is carried out with 500 c.c. of the sample in a copper vessel, tapering from 6 ins. to 4½ ins. in diameter and 6 ins. high in the body, and fitted with an eight-section Young-Thomas column. The distillate should distil over fairly rapidly, but not in a continuous stream, and is collected up to 165° C., the residue being heavy oil or cresote. In the case of crude naphtha or light oils, the tar acids may be removed by washing with caustic soda. The distillate is then washed as follows:—Carbon bisulphide is removed by agitation with 30 c.c. of 10% alcoholic potash, the potassium xanthate being removed by three water-washes of 100 c.c., 50 c.c., and 30 c.c. Unsaturated compounds, bases, etc., are removed by washing with 20 c.c. of sulphuric acid (C.O.N.) per 250 c.c. of distillate for 5 minutes, the acid being run off after standing for half an hour. Phenolic substances are removed by agitation with 20 c.c. of 10% caustic soda solution per 250 c.c. of distillate. The soda layer is run off after standing for half an hour and excess soda washed out by gentle shaking with water. The oil is dried by standing over calcium chloride overnight. The dried and purified oil is fractionated in the same vessel and column, the following fractions being collected: (a) start to 85° C., (b) 85° to 105°, (c) 105° to 115°, (d) 115° to 165° C. The respective volumes are indicated by:—Benzene = $a + \frac{1}{2}b$; toluene = $\frac{1}{2}b + c$; solvent naphtha = d . The specific gravities of a , b , and c should be at least 0.883, 0.878, and 0.868 respec-

tively at 60° F. (15.5° C.), low specific gravities denoting the presence of paraffins, which may be approximately determined by the extent of the reduction.—J. E. C.

Phenol; Determination of—*in crude carbolic acid and coal-tar oils.* F. W. Skirrow. J. Ind. Eng. Chem., 1917, 9, 1102—1106.

The method is based upon the oxygen absorption values of phenol and the cresols (see this J., 1908, 58). To obtain standard values the solutions of phenol, etc., were diluted so as to contain 0.002 gm. in 50 c.c. Portions of 50 c.c. of potassium permanganate solution (0.395 gm. per litre) were treated with 15 c.c. of dilute (1:3) sulphuric acid (faintly tinged with permanganate), and the bottles closed and placed in a thermostat at 23° C. The solutions of tar acids, etc., were also brought to 23° C., and 50 c.c. run from a pipette heated to 23° C. into the permanganate solution. The time was taken from the fall of the first drop, and the bottles were rapidly shaken, and allowed to stand for 3 mins., whereupon one c.c. of 10% potassium iodide solution was introduced, the liberated iodine titrated with thiosulphate solution (7 grms.

allowed to stand for 5 mins. It was then cooled under the tap, the mixture slightly acidified with sulphuric acid, the excess of iodine removed by means of a slight excess of thiosulphate, and the precipitated iodine compound washed once by decantation, and transferred to a weighing bottle of clear glass for comparison. The method was applied to the distillates obtained by three successive fractionations of crude carbolic acid, and the results are tabulated. Other samples of crude carbolic and refined cresylic acids were freed from hydrogen sulphide, fractionated twice, and the fractions examined as described. It was found that the mean oxygen absorption of the cresols, etc., in these fractions, calculated from the oxygen absorption of the fraction, the oxygen absorption of pure phenol, and the percentage of phenol found in the fraction, was very constant in each fraction, and that the variations in the oxygen absorption were mainly due to the variations in the amount of phenol. For example, the mean oxygen absorptions of the cresols, etc. (constituents other than phenol), in the fractions from the second fractionation of a litre of the various samples were as follows:—

No.	Temp., ° C.	Crude carbolic acid.	Refined cresylic acid.	Carbolic acid, "60's."	Refined cresylic acid.	Crude carbolic acid.	Mean.
1	180—184	1.117	1.120	1.118	(1.110)	1.114	1.117
2	184—187	1.114	1.119	1.113	1.113	1.115	1.115
3	187—190	1.096	1.099	1.102	1.097	1.099	1.099
4	190—193	1.083	1.081	1.077	1.088	1.082	1.082
5	193—196	1.076	1.078	1.076	1.084	1.076	1.078
6	196—199	1.073	1.078	1.070	1.069	1.062	1.070

per litre), and the results calculated to grms. of oxygen absorbed by 1 gm. of the respective substances. The following mean values were thus obtained:—Phenol, 1.134; *o*-cresol, 1.170; *m*-cresol, 1.156; and *p*-cresol, 1.062 gm. Test experiments with solutions containing from 11 to 89% of phenol and mixtures in equal proportions of the three cresols gave slightly increased oxidation values, but not sufficient to invalidate the method. The differences in the rates of oxidation of the three cresols is, however, too great to allow of the application of the method unless the ratio in which they are present is known. It is therefore necessary to fractionate the crude carbolic acid by distillation, and to determine approximately the amounts of the three cresols in the fractions in which the phenol is concentrated. The "pear" still-head, as used by Weiss and Downs (this J., 1917, 863), gave the best results for the fractionation, and there was no advantage in making more than two fractionations. For estimating the relative proportions of phenol and cresols in the several fractions an adaptation of Messinger and Vortmann's method of determining phenol as triiodophenol was used. The final iodine products have the following colorations:—Phenol, rose-pink; *o*-cresol, brown; *m*-cresol, slate-blue; and *p*-cresol, dirty yellow. By determining the oxygen absorption value of a mixture of phenol and cresols, and making trial mixtures of the same oxygen absorption value, it was possible eventually to match the shade given by the iodine compound of the unknown mixture. In the case of the higher fractions, better colour comparisons can be made by using mixtures with slightly higher oxygen absorption than the fractions to be matched, this being probably due to the increasing amounts of substances of higher b. pt. in those fractions. For the preparation of the iodo-compound, 25 c.c. of a solution of 1 gm. of the mixture of phenol and cresols in 500 c.c. of water was added to 3.5 c.c. of *N*/1 sodium hydroxide diluted with 200 c.c. of water, the mixture heated to 70° C. in a stoppered flask, 25 c.c. of 0.02 *N* iodine solution added, and the flask shaken and

Hence the percentage of phenol in each fraction may be calculated from the oxygen absorption of pure phenol and the mean oxygen absorption of the cresol, etc., in that fraction, as given in the table, without the tedious matching operations described above. Small errors are caused by the presence of pyridine, and by water retained by the dissolved sodium phenolate. These errors are corrected by adding the following amounts to the percentages of phenol:—9.62%, 0.38; 23.98%, 1.02; 47.50%, 2.50; and 70.54%, 4.46%. With this correction the results thus obtained agree within 0.2 to 0.3% of the true amounts of phenol. The method may also be used for the determination of phenol in the tar acids from inclined retorts, vertical retorts, blast furnace creosote, and producer gas tar.—C. A. M.

Use of crude naphthalene as fuel for internal combustion engines. Willis. See IIA.

PATENTS.

Distillation and dehydration of coal tar, mineral or vegetable oils and the like and debenzolising of wash and other oils and liquids; Apparatus for the—T. C. Hammond and C. K. Richardson, Huddersfield, Yorks. Eng. Pat. 111,956, Mar. 5, 1917. (Appl. No. 3196 of 1917.)

In the upper part of a still is a preheater comprising a series of overlapping baffle-plates arranged in step fashion. The crude tar or oil, fed on to the uppermost plate, flows down the series. The lighter portions (light oils, water, etc.) are vaporised and removed through an outlet pipe. From the lowest step, the tar or oil passes into the still proper, whence it is drawn off through a suitable opening. Vapours given off from the still pass between the baffle-plates of the preheater, which thus serves also as a fractionating column, the heavier portions, which may be produced by local overheating, dropping back into the still.—L. A. C.

Condenser and heat interchanger [for tar distillation]; Combined—C. K. Richardson and T. C. Hammond, Huddersfield. Eng. Pat. 111,961, Mar. 14, 1917. (Appl. No. 3689 of 1917.)

THE apparatus consists of a vertical tubular condenser, the tube chamber being surrounded by an annular jacket. The apparatus is specially applicable to dehydrating or distilling tar, and when so used the vapours from the still are passed down the tubes and the crude cold tar is passed upwards around the tubes. The hot dehydrated tar or other hot liquid is passed downwards through the annular jacket and serves to assist in heating the crude tar.—W. H. C.

Naphthalene; Sublimation of—R. C. Taylor, Manchester. Eng. Pat. 111,774, Mar. 2, 1917. (Appl. No. 3104 of 1917.)

CRUDE naphthalene is heated in a stationary tank provided with a mechanical stirrer, above which are a number of condensing chambers. A rotatable pipe with a cut away portion serves as a valve to connect the tank with each of the condensing chambers in turn, so that sublimate of different qualities can be collected.—F. W. A.

Chlorine derivatives of toluol [benzyl and benzal chlorides and benzotrichloride]; Manufacturing side-chain—H. D. Gibbs, San Francisco, Cal., and G. A. Geiger, Washington, D.C. U.S. Pat. 1,246,739, Nov. 13, 1917. Date of appl., Mar. 20, 1917. (Dedicated to the public.)

GASEOUS toluol and chlorine in theoretical proportions are introduced at a measured velocity into a suitable reaction chamber in which they are subjected to the action of ultra-violet rays. One mol. equiv. of toluol with one, two, and three mol. equivs. of chlorine produce respectively benzyl chloride, benzal chloride, and benzotrichloride.—L. A. C.

Sulphonation of aromatic hydrocarbons or their derivatives; Process for the—H. Bull, Philadelphia, Pa. U.S. Pat. 1,247,499, Nov. 20, 1917. Date of appl., Sept. 2, 1916.

AROMATIC hydrocarbons or their derivatives are sulphonated in the presence of an organic solvent, of lower specific gravity than sulphuric acid, in which the substance and sulphonated product are soluble but the sulphuric acid is not appreciably soluble, and the solution of the sulphonated product is removed. The solvent may consist of an excess of the aromatic hydrocarbon, and the process may be made continuous by continuously removing the extracted sulphonated product.

The physical basis of colour-technology. Luckiesh. See XIII.

PATENTS.

Dyes from natural products; Production of—J. B. Duarte, S. Paulo, Brazil. Eng. Pat. 106,815, Jan. 30, 1917. (Appl. No. 1516 of 1917.) Under Int. Conv., May 31, 1916.

WASHED pulverised or unpulverised leaves of one or more of the mangrove species of the genus

Rhizophora are infused, macerated, digested, or decocted, and the liquid filtered or separated by a centrifuge, and concentrated *in vacuo* or otherwise, sodium or potassium bisulphite and other salts being subsequently added. The product ("Ingletina C") is composed of tannins, sodium chloride, mucilage, and non-classified colouring and resinous materials, giving when treated with alkalis and metallic salts a range of colours including black and chestnut and a number of coloured lakes applicable to fibres and textiles, and resistant to light and washing.—F. W. A.

Colouring matters [sulphur dyestuffs]; Manufacture of—[from residues from manufacture of trinitrotoluene], O. Silberrad, Buckhurst Hill, Essex. Eng. Pat. 111,738, Dec. 28, 1916. (Appl. No. 18,547 of 1916.)

RESIDUES obtained in the purification of trinitrotoluene, containing 2,3- and 3,4-dinitrotoluene and 2,3,4- and 3,4,6-trinitrotoluene, are fused with sodium sulphide and sulphur. The product dyes cotton direct a fine deep khaki brown from a sodium sulphide bath.—F. W. A.

Vat dyestuffs; Process for producing—S. Sokal, London. From Kalle and Co. A.-G., Biebrich, Germany. Eng. Pat. 111,904, Dec. 14, 1916. (Appl. No. 17,982 of 1916.)

V.—FIBRES; TEXTILES; CELLULOSE; PAPER.

Sulphite cellulose; Constitution and stability of various lyes used in the manufacture of—and their specific action in the decomposition of wood. T. Marusawa, Kōgyō-Kvagakū-Zasshi (J. Chem. Ind., Tokyo), 1917, 20, 737—773.

SOLUTIONS of sulphurous acid undergo considerable decomposition even at 130° C., a solution containing 0.6 gm.-mol. per litre of H₂SO₃ being decomposed to the extent of 25% in 13 hours at that temperature, or in 2 hours at 150° C. After 6 hours at 150° C. about 42% of the acid is decomposed, mainly into sulphur and sulphuric acid, with a small amount of thiosulphuric acid. The addition of selenium has no appreciable influence on the rate of decomposition. A solution of sodium or ammonium bisulphite is very stable, a solution containing 0.6 gm.-mol. per litre, for example, being decomposed only to the extent of a few per cent. after 6 hours at 150° C., and of about 14% at 170° C., but in no case is sulphur separated. Below 150° C. the addition of selenium has practically no influence. A solution of sulphurous acid containing sodium or ammonium bisulphite is fairly stable below 150° C., and a solution containing 0.3 gm.-mol. per litre of each component undergoes only about 10% decomposition after 6 hours' heating at that temperature, whilst no sulphur separates. The rate of decomposition increases rapidly with the rise of temperature, the decomposition being practically complete after 6 hours' heating at 170° C. Selenium has a pronounced influence on the decomposition of the mixture, so that when heated for 6 hours at 150° C., with 0.01 gm. of selenium per litre, it is decomposed to the extent of over 80%, whilst a large amount of sulphur separates. Under parallel conditions the stability of the mixture decreases with the rise in the ratio of free sulphurous acid to bisulphite, independently of the presence or

absence of selenium. If a mixture of sulphurous acid and calcium bisulphite of the composition usually employed in sulphite-cellulose works is heated in a closed vessel calcium sulphite separates. To prevent this, the composition of the mixture must be so regulated that the ratio $\text{H}_2\text{SO}_3 : 2\text{Ca}(\text{HSO}_3)_2$ exceeds a certain critical point. Other conditions being similar, this value depends upon the temperature and increases with the rise of temperature. For example, in the case of a solution containing 0.13 grm.-mol. per litre of calcium, the critical values at 100° and 140° C. were 1.1 and 1.6 respectively, when the volume of the solution was $\frac{1}{2}$ that of the vessel. The conditions of decomposition of the mixture of calcium bisulphite and sulphurous acid are similar to those described for sodium and ammonium bisulphites. In course of time the calcium sulphite which first separates, as mentioned above, redissolves, whilst calcium sulphate is formed as a new deposit. The primary decomposition of sulphurous acid probably occurs in its dissociated part, HSO_3 , and is accelerated by hydrogen ions, and the stability of bisulphite solution, notwithstanding its high HSO_3 content, must be attributed to the want of an accelerator of the decomposition, owing to the very slight concentration of hydrogen ions. The action of selenium may be explained by the assumption that it forms with bisulphite, or more probably with HSO_3 , an unknown compound, which in the presence of H^+ is exceedingly unstable.—C. A. M.

Polish lye from vegetable ashes; Manufacture of —, and its application for boiling straw in the paper industry. S. Tanaka. Kōgyō-Kwagaku-Zasshi (J. Chem. Ind., Tokyo), 1917, 20, 844—850.

ASHES from vegetable matters have been investigated from the point of view of the manufacture of caustic potash for the digestion of straw for paper making. Ashes from soy bean pods contained 16.49% of potassium carbonate and from chestnuts, 13.96%. For the manufacture of caustic potash it is necessary that the ashes should contain more than 10% of potassium carbonate. Lime may be added directly to the solution of ash in water without separating the insoluble residue. The yield of caustic potash depends very largely on the perfection of the filtration and lixiviation processes. The potash obtained is quite efficient for the manufacture of straw pulp and its substitution for caustic soda is a question of cost. A constant and sufficient supply of potash from these sources is hardly to be expected and the difficulties of the filtration process increase the cost.—J. F. B.

Distillation of cellulose and starch in vacuo. Pietet and Sarasin. See II B.

Silk; Process for increasing the strength and elasticity and for preventing or decreasing the subsequent weakening of non-loaded raw or boiled fibres in —. J. Korseit, Zittau, Saxony. Eng. Pat. 104,684, Mar. 5, 1917. (Appl. No. 3249 of 1917.) Under Int. Conv., Feb. 5, 1916.

THE silk is treated with alkaloids or with products of the decomposition of alkaloids which have a more complex molecule than urea and hexamethylenetetramine, especially with derivatives of pyridine, piperidine, pyrrole, pyrrolidine, quinoline, isoquinoline, phenanthrene, morpholine, or purine, provided these products do not modify the feel and appearance of the silk and provided they do not give any undesirable colour-reaction with iron

compounds. The silk is treated for 30 mins. at the ordinary temperature, or warm (up to 40° C.), in a solution containing from 1 to 10% of the alkaloid or its salt, e.g., cinchonine, caffeine hydrochloride, or carboethinomeronic acid, calculated on the weight of the silk. The increase in strength of the silk may be 10–50% according to the quantity of alkaloid used, and the substances named act in a protective sense against oxidising influences.—J. F. B.

Textile belting and method of preparing the same. H. St. L. Buchner, Wollaston, Mass. U.S. Pat. 1,249,019, Dec. 4, 1917. Date of appl., Dec. 18, 1916.

TEXTILE belting, driving tapes, and the like are saturated with a mixture of equal parts of refined oil asphalt and refined petroleum distillate, or asphaltic base lubricating oil by immersion therein at about 200° F. (93.5° C.).—J. F. B.

Metallic yarn and method of treating same to facilitate weaving and for other purposes. W. H. Underwood, New York. U.S. Pat. 1,249,252, Dec. 4, 1917. Date of appl., Dec. 30, 1914.

IN the manufacture of woven fabric containing rough metallic yarn, the yarn is coated before weaving with a material to fill the spaces in the surface of the fibres of which the yarn is made. The fibres of the metallic yarn may be coated with lead or the fabric may be made from spun metallic wool coated with a metal which resists the action of sulphur, or, generally, the fibres of the metallic yarn are treated with a corrosion-resisting material before weaving.

—J. F. B.

[Plastic fibrous] material capable of being cast or moulded by extrusion, rolling or other suitable means and the method of manufacturing same. H. Jackson, Garstang, Lancs. Eng. Pat. 111,946, Jan. 26, 1917. (Appl. No. 1319 of 1917.)

FIBROUS material is reduced to a pulp and the major portion of the water is removed from the pulp by draining or by a hydro-extractor. The moist pulp is mixed with a dry powdered glutinous or gelatinous substance such as gum, starch, or glue, then heated, preferably in a closed vessel at 165°–212° F. (74°–100° C.). A plastic mass of pulped material is thus produced which may be formed in any desired shape by squirting, pressing, or rolling.—J. F. B.

Fibrous plastic composition and process of making same. C. Ellis, Montclair, N.J., Assignor to Ellis-Foster Co. U.S. Pat. 1,246,806, Nov. 13, 1917. Date of appl., Apr. 30, 1917.

THE solids in acid sulphite-cellulose waste liquor are precipitated in contact with fibrous material.

—B. N.

[Wood] pulp; Manufacture of chemical sulphate —. C. N. Waite and J. E. Hedin, Wilmington, Del., Assignors to W. H. Sharp, Philadelphia, Pa. U.S. Pat. 1,249,287, Dec. 4, 1917. Date of appl., Feb. 3, 1914.

LIQUOR for the digestion of wood pulp is prepared from the spent liquor of a previous digestion by evaporating the water, burning off the organic matter, and dissolving the sodium carbonate in the ash, at the same time adding lime to causticise the soda and sufficient sulphur to convert part of the caustic soda into sodium sulphide.—J. F. B.

VII.—ACIDS; ALKALIS; SALTS; NON-METALLIC ELEMENTS.

Ammonia oxidation process; Analytical control of —. G. B. Taylor and J. D. Davis. J. Ind. Eng. Chem., 1917, 9, 1106—1110. (See also Fox, this J., 1917, 1005.)

The efficiency of an ammonia converter depends upon the establishment of conditions favourable to the reaction—

and unfavourable to the reaction—

and if nitric acid is to be the ultimate product little ammonia should be allowed to pass unchanged through the converter. The efficiency calculation is based upon the principle that the ratio of the nitrogen in combination as ammonia to the total nitrogen in the intake gas is equal to the ratio of the nitrogen derived from the ammonia to the total nitrogen in the exit gas. Hence the efficiency of a plant may be expressed by the equation—

$$\frac{c(a+b)}{a(c+d+f)} \times 100 \quad \text{per cent. yield.}$$

where a represents the nitrogen as ammonia and b the free nitrogen in the initial mixture of air and ammonia, c the nitrogen combined as nitrogen oxides, d the free nitrogen, and f the nitrogen combined as ammonia escaping oxidation in the exit gas. The most convenient method of controlling the process is to take samples of the gases in exhausted bottles of known capacity, provided with single capillary stopcocks, and with ground glass stoppers. Sufficient $N/5$ sulphuric acid to neutralise the ammonia is admitted to the ammonia-air sample, and a measured quantity of water after absorption of the ammonia until the residual air is at atmospheric pressure, and the excess of acid is then titrated to obtain a . A measured volume of water containing hydrogen peroxide is drawn into the bottle containing the sample of reaction products to absorb acid vapours, and analysis of the residual mixture of oxygen and nitrogen gives the proportion of free nitrogen, d . The acid solution is titrated with $N/5$ sodium hydroxide solution, and then distilled with sodium hydroxide into $N/5$ sulphuric acid to obtain the amount of ammonia, f . Since this ammonia was present as nitrate, its equivalent is added to the free acid already determined for the calculation of c . To ascertain whether there is a leak between the point where the ammonia-air sample is taken and the point where the nitrous gases are sampled, the amount of oxygen admitted

to the sample of nitrous gas is measured, and water containing a measured quantity of hydrogen peroxide is introduced. The whole of the combined nitrogen will then be present as nitric acid. After determination of the excess of oxygen gas the liquid is divided into two parts, in one of which the acid is titrated with alkali whilst in the other the excess of hydrogen peroxide is determined by means of standard permanganate solution. The amount of oxygen required for the oxidation of the ammonia converted can then be calculated, and any excess will be due to leakage. Analysis of the intake gas of ammonia and air may also be made by the ordinary gas analysis methods, the ammonia being dried by passing it through a U-tube filled with pieces of solid potassium hydroxide, and absorbed in a bulb form of graduated burette by means of concentrated sulphuric acid, dry mercury being used as the confining liquid.—C. A. M.

Nitrogen-hydrogen equilibrium; Effect of hydrogen chloride on the —. E. B. Ludlam. Faraday Soc., Feb., 1917. [Reprint.] 10 pp.

THE early experiments of Deville on the vapour density of ammonium chloride at high temperatures suggest that ammonia is far more stable in the presence than in the absence of hydrogen chloride. The large evolution of heat and the marked volume contraction attending the formation of ammonium chloride from its elements suggest also that the conditions are more favourable to a union of nitrogen and hydrogen than when hydrogen chloride is absent. Synthetic experiments, at atmospheric pressure, with nitrogen and hydrogen in presence of hydrogen chloride, at various temperatures from 500° to 1500° C., were carried out with negative results. Equilibrium was approached much too slowly. Attempts were made to attain equilibrium from the other side by heating ammonium chloride alone to various temperatures up to 1200° C., in presence of a number of metallic catalysts such as gold, silver, zinc, copper, iron. The decomposition of ammonium chloride was found to be almost complete after 5 hours at 800° C. in presence of iron, showing that ammonium chloride is not stable at high temperatures. Its apparent stability is due to a very slow rate of decomposition. Synthetic experiments at 450° C. in presence of iron failed to show any advantage due to hydrogen chloride, but since the iron was all removed by volatilisation as ferrous chloride the question still remains open.—H. J. H.

Potash: A neglected chemical reaction and an available source of —. E. A. Ashcroft. Inst. Min. and Met., Dec. 20, 1917. [Advance proof.] 20 pages.

THERE is a reversible reaction between dry sodium chloride and orthoclase felspar when heated together in a state of fine division in the absence of air or moisture. In the state of equilibrium the distribution of the alkalis depends on their relative proportions: $-2\text{NaCl} + \text{K}_2\text{O} \cdot \text{Al}_2\text{O}_3 \cdot 6\text{SiO}_2 = \text{Na}_2\text{O} \cdot \text{Al}_2\text{O}_3 \cdot 6\text{SiO}_2 + 2\text{KCl}$. If the felspar (10% K_2O), crushed to pass a 100-mesh (I.M.M.) sieve and mixed with its own weight of salt, is heated for 2 hours at 900°–1000° C., 85% of the potash will be converted into a soluble form without loss by volatilisation. A temperature above 1100° C. is to be avoided as conducing to fritting, while the presence of air and moisture leads to loss of alkali and destruction of any metal containers by chlorine and hydrogen chloride evolved. The reversibility of the reaction was demonstrated by heating the product of the above reaction with excess of potassium chloride, when the potash felspar was regenerated. The product of the direct reaction as above yields on lixivitation a

mixture containing about 90% of NaCl and 10% of KCl, which can be separated by crystallisation. It is suggested that the reaction should be applied to the extraction of potash from British felspars. Apart from the expensive high-grade felspars used in pottery manufacture, there is a large quantity, estimated at 20,000,000 tons at least, of pegmatite exposed on the extreme north-west coast of Sutherlandshire, Scotland. It contains 8% of K_2O and its estimated cost, quarried and picked, is 2s. 6d. per ton, on a site well suited for the erection of works for treatment and favourable as regards conditions of water-borne transport. It is suggested that a form of vertical retort might be used in which molten salt percolates a heated charge of felspar. Alternatively the charge might be placed in iron boats, closed with lids, and pushed through a heated horizontal gas retort in which an atmosphere of producer-gas is maintained. The boats would form a continuous train and would remain for 2 hours in the hot zone and $\frac{1}{2}$ hour in the cooling region. It is estimated that 80% KCl could be produced in normal times at a cost of £7 per ton, thus competing favourably with German supplies. The analytical methods for dealing with mixtures of potassium and sodium chlorides are discussed. The "indirect method" based on the estimation of the total chlorine is recommended as accurate to within 1% if care is taken and the mixture titrated against silver nitrate is free from chlorides of other metals. Iron, manganese, calcium, and magnesium are removed by boiling first with ammonium carbonate and filtering, then with a crystal of oxalic acid, and again filtering, and evaporating to dryness with hydrochloric acid. The residue dissolved in water is titrated with $N/10$ silver nitrate, using weak chromic acid solution as indicator.—H. J. H.

Sodium cyanide; Hydrolysis of —. F. P. Worley and V. R. Browne. *Chem. Soc. Trans.*, 1917, 111, 1057—1062.

THE hydrolysis of sodium cyanide was measured by comparing the concentration of hydrogen cyanide vapour above solutions of sodium cyanide and of hydrogen cyanide. Air was drawn at the rate of one bubble per second through caustic soda solution to remove carbon dioxide, and then through the following solutions in series in the order given, hydrocyanic acid—indicator—sodium cyanide—indicator—hydrocyanic acid—indicator. The indicator was a solution containing 0.2% of picric acid and 2% of sodium carbonate. With hydrogen cyanide vapour it gives a reddish-brown coloration, the depth of which depends on the concentration of the vapour. The concentrations of the hydrocyanic acid solutions on each side of the sodium cyanide solution were adjusted until one had a vapour pressure just above and the other just below that of the sodium cyanide solution. The degree of hydrolysis of the latter was then defined between narrow limits. From the equation $NaCN + H_2O \rightleftharpoons NaOH + HCN$, it follows that when the water is in large excess— $\text{conc. of NaOH} \times \text{conc. of HCN} = \text{conc. of NaCN} \times K$. If neither alkali nor acid is added, and C is the concentration of total sodium cyanide, and P the percentage hydrolysed,

$$\frac{P^2C}{100(100-P)} = K.$$

Experiments at 25°C. on solutions of sodium cyanide varying in strength from 5.2 to 0.0073 gm.-mol. per litre gave the value of $K \times 10^4 = 0.484$. The percentage hydrolysis of a solution containing 0.0435 gm.-mol. of sodium cyanide per litre, when different amounts of caustic soda

and hydrochloric acid were added per gm.-mol. of sodium cyanide, varied from 0.11% for 1 gm.-mol. of caustic soda to 2.8% for 0.01 gm.-mol. of caustic soda, and from 10.9% for 0.1 gm.-mol. of hydrochloric acid to 40.175% for 0.4 gm.-mol. of hydrochloric acid. The value of $K \times 10^4$ varied from 0.135 at 0°C. to 0.72 at 30°C.—F. Sp.

Polysulphides of alkali metals. Part III. Solidifying points of the systems sodium monosulphide-sulphur and potassium monosulphide-sulphur. J. S. Thomas and A. Rule. *Chem. Soc. Trans.*, 1917, 111, 1063—1085.

TO ascertain the number and the relative stability of the solid polysulphides of sodium and potassium, the freezing-point curves of the systems sodium monosulphide-sulphur and potassium monosulphide-sulphur, and the rate of desulphurisation of the higher polysulphides in a stream of hydrogen at regularly increasing temperatures, have been determined. The results indicate the existence of a complete series of compounds of the general formula R_2S_x , where x is a whole number having the maximum value 5 in the sodium series and 6 in the potassium series. No evidence was obtained of the existence of intermediate compounds, such as the enneasulphide described by Bloxam (this J., 1899, 684). The variation in the rate of loss of sulphur of sodium tetrasulphide on heating in a current of hydrogen indicates that it undergoes considerable decomposition below 300°C., and then loses sulphur regularly until the composition of the fusion approaches that of the disulphide, between 625° and 650°C. The disulphide is much more stable to heat than the higher sulphides. Potassium pentasulphide shows practically the same behaviour, but there is a slight retardation in the loss of sulphur in the region where the composition of the fusion approximates to that of the trisulphide. The disulphide is the most stable of the potassium polysulphides. None of the results obtained supported Bloxam's view (*loc. cit.*) that the polysulphides should be represented by the formula R_2S_x , and determinations of the molecular weights in alcohol, by the ebullioscopic method, of sodium disulphide, sodium tetrasulphide, and potassium pentasulphide, gave in all cases results lower even than those demanded by the simple formula R_2S_x . To explain the stability of the disulphides, the authors suggest the formula $R.S.S.R.$, the trisulphides being $S:(R)S.S.R.$ and the tetrasulphides $S:(R)S.S(R):S$.—F. Sp.

Rare earths; Observations on the —. IV. *Purification of gadolinium.* L. Jordan and B. S. Hopkins. *J. Amer. Chem. Soc.*, 1917, 39, 2614—2623.

THE fractional crystallisation of dimethylphosphates, bromates, and glycolates of the rare earths has been examined with a view to the separation of pure gadolinium from rare earth mixtures. Fractionation of the dimethylphosphates quickly removes europium and samarium, and from the middle fractions, which are very rich in gadolinium, terbium may be removed by fractionation of the bromates. The method of procedure recommended for the separation of gadolinium from rare earth mixtures is to remove cerium by the bromate method. The residual bromates are fractionally crystallised. The less soluble fractions, containing only europium, samarium, gadolinium, and neodymium, are converted into the dimethylphosphates, and on fractionation, the least soluble fraction consists of high-grade gadolinium. Any remaining traces of samarium can be removed by precipitation with sodium glycolate.—H. M. D.

Tartrates ; Test for—depending upon the formation of the copper-tartrate complex. L. J. Curtman, A. Lewis, and B. R. Harris. J. Amer. Chem. Soc., 1917, **39**, 2623—2630.

A SYSTEMATIC examination of the alkaline copper test for tartrates has led the authors to recommend the following procedure. To 5 c.c. of the solution is added 3 c.c. of a 2.5% solution of sodium hyaroxide and 1 c.c. of *N*/5 copper sulphide. The volume is made up to 10 c.c. and the mixture shaken for 1 minute. The mixture is then filtered, the filtrate acidified with 50% acetic acid, one drop of potassium ferrocyanide solution added, and the difference noted after 1 minute. According to the quantity of tartrate present, a pink coloration or a reddish-brown precipitate makes its appearance. It is possible to detect 0.2 mgrm. of tartrate in this way and the use of ferrocyanide, in place of ammonia, makes the test appreciably more sensitive. Solutions which contain ammonium salts, arsenites, borates, or phosphates give a positive reaction in the absence of tartrates. If the quantity of tartrate is small, the reaction is observed in the presence of thiosulphates, arsenates, chromates, fluorides, thiocyanates, nitrites, oxalates, and acetates.—H. M. D.

Silica ; Solubility of—V. Lenher and H. B. Merrill. J. Amer. Chem. Soc., 1917, **39**, 2630—2638.

THE solubility of silica in water and acid solutions is a factor of importance in connection with the analytical estimation of silica, and measurements have accordingly been made of the solubility in water, and in solutions of hydrochloric and sulphuric acid at 25° and 90° C. With gelatinous silica, saturation is reached after a few hours or days, but with ignited silica the attainment of equilibrium requires a much longer time. The results obtained show that the solubility of gelatinous silica is independent of the mode of preparation of the substance, and that ignited silica tends towards the same limit in respect of the concentration. The solubility increases with the temperature, and at a fixed temperature, decreases with increase in the concentration of the mineral acid. Carbonic acid has no measurable influence on the solubility of silica. At 90° C. the solubility of gelatinous silica in grms. per 50 c.c. is 0.0212—0.0216 grm. in conductivity water, 0.024 grm. in 1.2% HCl, 0.0028 in 18.7% HCl, 0.0211 in 3.9% H₂SO₄, and 0.0004 in 71% H₂SO₄. At 25° C., the solubility figures obtained after digesting for 2 days were: water, 0.0032; 6.4% HCl, 0.0044; and 34.9% HCl, 0.004 grm. per 50 c.c.

Acid-collecting apparatus. E. T. Keller, City Point, Va. U.S. Pat. 1,247,280, Nov. 20, 1917. Date of appl., Jan. 10, 1917.

AN arrangement of a series of towers is provided with reversely arranged baffles having spiral, radially disposed deflecting blades, in which the acid fumes pass upwards and the washing liquid downwards. The gas outlet of one tower is connected with the inlet of the next, and the acid liquid, collected in a chamber at the bottom of one

tower, is elevated to the distributing chamber of the next and sprayed into the tower under pressure.
—B. V. S.

Nitre-cake ; Utilisation of—J. Grossmann, Manchester. Eng. Pat. 111,875, Nov. 18, 1916. (Appl. No. 16,555 of 1916.)

By heating a mixture of sodium nitrate, nitre cake, and carbonaceous material in suitable proportions to about 250° C., the nitrogen is evolved almost entirely as nitric acid or oxides easily oxidised to nitric acid, there being no nitrogen or nitrous oxide formed; the residue is an easily friable form of slightly acid sodium sulphate with carbonaceous material. The process may be conducted at ordinary, increased, or reduced pressure, and air may be blown or drawn through part or all of the system. The evolved nitrous gases may be treated with air and steam for the production of nitric acid or passed to a sulphuric acid plant, etc.—B. V. S.

Ammonia and potassium-containing material from tobacco waste ; Process of producing—J. E. Zilk. Assignor to Odorless Fertilizer Manufacturing Co., Pittsburgh, Pa. U.S. Pat. 1,247,060, Nov. 20, 1917. Date of appl., Feb. 10, 1917.

TOBACCO waste is decomposed by heat in the absence of air. The charcoal residue contains water-soluble potassium compounds. The gases are withdrawn and heated further to convert the nitrogenous compounds into ammonia, which is recovered by condensation.—B. V. S.

Sodium silicofluoride ; Method of making—K. F. Stahl, Pittsburgh, Pa. U.S. Pat. 1,247,165, Nov. 20, 1917. Date of appl., Mar. 17, 1917.

A PHOSPHATE rock containing fluoride is treated with sulphuric acid, a soluble phosphate and silicon fluoride being formed. The silicon fluoride is converted into hydrofluosilicic acid which is treated with sodium sulphate with the production of sodium silicofluoride and sulphuric acid.—B. V. S.

Manganese carbonate ; Process for the oxidation of—M. L. Kaplan, Brooklyn, N.Y. U.S. Pat. 1,247,278, Nov. 20, 1917. Date of appl., Apr. 30, 1917.

MANGANESE carbonate is oxidised by heating at a temperature above 300° C. with nitric acid vapour or with air mixed with acid or mixed with nitrogen oxides containing a higher proportion of oxygen than nitric oxide.—B. V. S.

Alkali [from silicates] ; Recovery of—J. S. Beckett, Cranford, Assignor to P. R. Moses, New York. U.S. Pat. 1,247,619, Nov. 27, 1917. Date of appl., Apr. 24, 1916.

A SILICATE containing an alkali metal (potassium) is heated in a furnace with a basic compound and a chloride. The alkali (potassium) chloride thus formed is extracted with water and the solution electrolysed. The resulting chlorine is passed into a mixture of lime and potassium chloride; chlorate is formed and the greater part of it separated by crystallisation. The residue containing calcium chloride and the remainder of the potassium salt is used for the treatment of more silicate.—B. V. S.

Molybdenum disulphide ; Process for producing—D. L. Johnson, Los Angeles, Cal. U.S. Pat. 1,248,867, Dec. 4, 1917. Date of appl., July 7, 1917.

A MIXTURE of finely-divided sodium molybdate and sulphur, in the proportion of 200 parts of molybdenum trioxide and 250 parts of sulphur, is heated. The insoluble molybdenum disulphide is washed to free it from soluble substances, including compounds of phosphorus and arsenic which may have been present in the molybdate.
—B. V. S.

Magnesia; Process of obtaining —. H. McLoughlin, Assignor to F. D. Carthew, San Francisco, Cal. U.S. Pat. 1,218,880, Dec. 4, 1917. Date of appl., Feb. 9, 1916.

MAGNESITE containing silica is calcined to remove carbon dioxide and the resulting magnesia disintegrated by quenching while still hot. The coarse silica is removed by sifting and the residue is ground to pass a 30-mesh screen. A relatively pure magnesia is then separated by washing with a stream of water regulated to carry away the part of the mass having sp. gr. about 2.2 and to leave the part having sp. gr. 3 or higher.—B. V. S.

Aluminium compounds; Process for producing —. F. Langford, Eureka, Cal. U.S. Pat. 1,249,125, Dec. 4, 1917. Date of appl., Aug. 5, 1916.

CRUDE aluminium ores are extracted first with sulphurous acid and then with dilute sulphuric acid. The resulting solutions are mixed, filtered through redwood fibre, and evaporated to dryness, and the residue is calcined.—B. V. S.

Chlorine; [Electrolytic] process for the extraction of —. P. L. Hulin, Grenoble, France. U.S. Pat. 1,246,099, Nov. 13, 1917. Date of appl., Sep. 15, 1916.

A GASEOUS mixture containing chlorine is washed with a solution of ferrous chloride or other suitable lower chloride. The higher chloride thus produced is acidified with hydrochloric acid and electrolysed, with the formation of chlorine and the lower chloride which is utilised again.—B. V. S.

Process of producing alkali carbonate and hydraulic cement from alkaliferous silicate minerals. Eng. Pat. 103,290. See IX.

Stable carbonic acid solution and method of producing same. U.S. Pat. 1,247,334. See XIXA.

VIII.—GLASS; CERAMICS.

Chemical stoneware; Standardisation of —. H. Nielsen and J. R. Garrow. Chem. Trade J., 1918, 62, 3—5, 23—25.

THERE is no valid reason why almost every article made of chemical pottery should not be standardised almost as closely as are articles made of iron or steel, and the authors appeal to makers and users to adopt standard sizes. Stoneware is less homogeneous than a metal and less is known of its resistance to stress. The ultimate tensile strength of high-class vitreous pottery lies between 600 and 842 lb. per sq. in., 600 lb. being a safe figure for almost any vitreous stoneware used in this country for acid-resisting pipes. The wall-thickness, w , of a pipe of diameter, d , required to resist an internal pressure, p , per unit of area, the stoneware having an ultimate tensile strength, u , is

$$w = \frac{pd}{2u}$$

This wall-thickness is usually multiplied by a safety factor of 4. The force resisting the tendency to fracture a pipe in direction of its length, owing to the presence of right-angle bends, stopcocks, etc., is

$$\frac{\pi}{4} d^2 \times \rho$$

$$\frac{\pi}{4} \left\{ (d + 2w)^2 - d^2 \right\}$$

and this quotient divided into the ultimate tensile strength of the stoneware gives the factor of safety in a longitudinal direction.

Tables and diagrams are given of the suggested principal dimensions for standard pipes, bends,

T-pieces, cross-pieces, stopcocks, bib-cocks, and iron connecting clips. The wall-thickness of pipes of 1 and 1½ in. diameter are made slightly greater than the calculated values in order to facilitate manufacture. A conical buttressed flange is preferred to a flat one. Bends should have as large a radius as conveniently possible and as it is often desired to replace a bend by a T-piece, or *vice versa*, the same centre-distances should be used throughout. A centre distance equal to the internal diameter + 4 in. is suggested. The flanges of bends should be the same as those on straight pipes. For T-pieces and cross-pieces with unequal branches, the centre-distance for the unequal branch should be $\frac{1}{2}(a + a_1) + 4$ in., where a is the internal diameter of the equal branches, and a_1 that of the unequal branch. The wall-thickness and flanges of T-pieces and cross-pieces should be the same as in straight pipes. Stopcocks for liquids under pressure should be of as simple design as possible, and preferably of the same length as standard T-pieces. The plugs should be well secured by an adaptable bridge, as there is a considerable force tending to blow them out. They should be carefully ground by machinery and polished by hand. All cocks should be immersed in water, tested by compressed air, and then marked. In bibcocks, the spigot should be of ample size with a standard conical flange; the tangent to the angle of the cone to be ground into the container should be about 0.05. Three-way and other special cocks should be avoided where possible. An arrangement of standard T- and cross-pieces and plain cocks will serve the same purpose, be more reliable, and will cost less for repairs. Iron jointing flanges or clips may conveniently consist of two pieces bolted together, with a suitable packing between the metal and the stoneware. The faces of the two pieces should be machined to ensure an accurate fit, and the whole device should be boiled in pitch before use. All holes should be drilled and not cored. Packing rings for use between the stoneware pipes should be made from woven asbestos cloth or asbestos millboard which has been boiled for three hours in soft paraffin wax or soaked in a strong solution of sodium silicate. For hydrochloric acid, pure soft Para rubber rings may be used.—A. B. S.

Chemical stoneware; Standardisation of —. H. Griffiths. Chem. Trade J., Jan. 12, 1918.

THE formula suggested by Nielsen and Garrow (see preceding abstract) for calculating wall-thickness is applicable to thin cylinders such as boiler shells, but not to pipes the thickness of whose walls is of the same order of magnitude as the internal radius. The quality of chemical stoneware is so variable that standardisation of sizes in accordance with calculated values is impracticable unless an excessively high factor of safety is used. The first essential is the standardisation of material rather than of form.—A. B. S.

Porcelain glaze; The application of talc for —. S. Kaneshima. Kōgyō-Kwakaku-Zasshi (J. Chem. Ind., Tokyo), 1917, 20, 850—860.

THE influence of talc as a constituent of porcelain glaze has been studied by making up glazes in which MgO replaced CaO in equimolecular proportions, the other constituents being identical. The talc employed was obtained from S. Manchuria and had the composition SiO_2 , 65.32; MgO, 32.47; CaO, 0.72; Fe_2O_3 and Al_2O_3 , 0.12%. The calcium glazes employed for comparison were prepared with precipitated calcium carbonate, containing only a trace of iron. The other ingredients of the glazes were felspar, Gairome clay, and silica. A large number of mixtures were

made affording a wide range of comparative variations. The experiments showed that the talc glazes were more fusible than the calcium carbonate glazes but not so liable to overfuse, and the formation of bubbles in the finished glaze was of rarer occurrence. Talc glaze was generally more lustrous than calcium carbonate glaze, but the development of colour of underglaze pigments was less brilliant.—J. F. B.

The physical basis of colour technology. Luckiesh.

Forming molten glass or like material in cylindrical form; Apparatus for—E. C. R. Marks, London. From The Libbey Glass Co., Toledo, Ohio, U.S.A. Eng. Pat. 111,521, Nov. 29, 1916. (Appl. No. 17,132 of 1916.)

A SLIGHT modification of Eng. Pat. 110,642 of 1916 (this J., 1917, 1277). The molten glass flows on and around an inclined rotating mandrel contained within a heated shell made of refractory material, the sections of the shell and mandrel being adjusted to regulate the thickness of the walls of the cylinder. After leaving the mandrel the glass is drawn out to the required diameter. A hollow mandrel may be used and air blown through it to produce a tube.—A. B. S.

Strengthened glass; Manufacturing—S. Goldreich, C. A. McKerrow, and Splinterless Anti-Mist Glass Syndicate, Ltd., London. Eng. Pat. 111,539, Dec. 2, 1916. (Appl. No. 17,346 of 1916.)

STRENGTHENED glass is made by immersing a celluloid sheet in methylated spirit or its vapour for about 2 mins. and then placing it between two specially cleaned sheets of glass and pressing them together in a spring press under a pressure of about 100 lb. per sq. in. The press and its contents are then heated in an oven to 120° C. for 1 hour and are afterwards removed and allowed to cool very slowly. The celluloid will adhere uniformly to the glass and the edges may be sealed with a coat of lead paint or lacquer, or by other suitable means.—A. B. S.

Glass; Method of gathering—C. F. Cox, Bridgeton, N.J., U.S.A. Eng. Pat. 111,899, Dec. 11, 1916. (Appl. No. 17,791 of 1916.)

A GATHERING machine of the type described in Eng. Pat. 2992 of 1907 is used, comprising a system of suction devices or moulds mounted on the circumference of a rotating table. Each mould is brought in turn over an extension of the furnace containing the molten glass and is lowered below the surface of the glass, filled by suction, moved forward, and then withdrawn. This dipping and withdrawing of the moulds produces a circulation of the molten glass in the furnace, whereby the portion which has been chilled by the mould is moved into a hotter part of the furnace and re-heated. Drippings of surplus glass from the moulds are similarly circulated and re-heated.—A. B. S.

Glass manufacture. T. J. McCoy, Kane, Pa. U.S. Pat. 1,216,764, Nov. 13, 1917. Date of appl., Oct. 4, 1911.

A GLASS-MELTING tank-furnace is connected with a second tank. A counterbalanced device operated automatically maintains the surface of the glass at a constant level in the second tank and in gathering basins on its circumference. Means are provided for maintaining the glass in the second tank at a suitable temperature.—A. B. S.

Sheet-glass; Apparatus for making—J. Barnes, Assignor to S. R. Seybold, New Kensington, Pa. U.S. Pat. 1,247,617, Nov. 27, 1917. Date of appl., Mar. 21, 1917.

AN apparatus for making sheet glass comprises a furnace and an arrangement of rolls for withdrawing the molten glass from the furnace, partially forming it into a sheet, and passing it through a rubber having adjustable casings forming water-jackets and solid wooden blocks. The rubbing blocks may be brought to bear on the sheet of glass or removed from its path without affecting its position in the rolls. A Lehr, with conveyor, for receiving the sheet of glass, is placed near the outlet of the furnace, the conveyor and rolls being driven at the same speed.—A. B. S.

Sheet glass; Method and apparatus for making—J. W. Colburn, Assignor to The Toledo Glass Co., Toledo, Ohio. U.S. Pat. 1,248,809, Dec. 4, 1917. Date of appl., Jan. 8, 1916.

A SHEET of glass is drawn vertically from a molten mass, through a cooling space and thence into a heated space in which the sheet is bent at right angles over a roller, and the temperature of the horizontal portion of the sheet is then raised until it softens. The sheet is then gradually cooled. Previous to bending the sheet, one face of it may be hardened by cooling.—A. B. S.

Casting pottery and other like articles. B. J. Allen, Blythe Bridge, Staffs., and R. Y. Ames, Gidea Park, Essex. Eng. Pat. 111,643, July 14, 1917. (Appl. No. 10,238 of 1917.) Addition to Eng. Pat. 110,649, Dec. 4, 1916 (this J., 1917, 1274.)

THE ware is cast in moulds surrounded by a vacuum chamber, as previously described but, in addition, pressure is applied to the casting slip by means of compressed air or steam or by a suitable head of slip, so as to enhance the effect of the vacuum, expedite the manufacture, and improve the quality of the ware.—A. B. S.

Depositing clay, plumbago and other like products on absorbent moulds. Manufacture of clay, plumbago, and other like articles by electro-deposition on metal moulds. B. J. Allen, Stoke-on-Trent. Eng. Pats. (A) 111,762, Feb. 15, 1917 (Appl. No. 2252 of 1917), and (B) 111,775, Mar. 3, 1917 (Appl. No. 3160 of 1917).

(A) THE material to be deposited is made into a slip with the suitable addition of acid or alkali and water, and is poured into a plaster mould provided with a vacuum chamber as described in Eng. Pat. 110,649 of 1916 (this J., 1917, 1274). An electric current is then passed through the mould and slip by connecting one wire to the outside of the mould and the other to an electrode immersed in the slip. The current causes the particles in suspension in the slip to travel towards the outside of the mould, and they are eventually deposited on the interior of the mould. A clear liquid accumulates around the immersed electrode and may be siphoned off, leaving the clay or other material deposited in the required shape. The density of the deposit may be reduced by reversing the electric current, or the attracting electrode may be applied to the parts of the deposit which are required to be thickest and the repelling (internal) electrode to those which are required to be thinnest. Reversing the electric current also facilitates the removal of the article from the mould. (B) In making articles of silica and plumbago by the process described above, it is not necessary to use absorbent moulds, and the material may be deposited directly on the metal electrode, which is shaped to give the formation of the desired article. The current required is of the order of 50 to 70 amperes at 50 to 100 volts.

being dependent on the material to be deposited. The process is applicable to the manufacture of crucibles, muffles, tubes, cores for furnaces, etc.—A. B. S.

Refractory [material] and process of making same. J. O. Handy and R. M. Isham. Assignors to A. S. Davison Co., Pittsburgh, Pa. U.S. Pat. 1,218,486, Dec. 4, 1917. Date of appl. Mar. 29, 1917.

DEAD-BURNED dolomite is converted into a sintered material which resists the action of boiling water by mixing it with a temporary binder, moulding it into bricks, and burning at a high temperature.—A. B. S.

Bricks and other moulded articles. H. W. Charlton, Jonespoint, N.Y. U.S. Pat. 1,249,028, Dec. 4, 1917. Date of appl. Apr. 28, 1917.

BRICKS or other articles made by moulding a mixture of rock material with a binder, obtained by digesting silicate material, such as feldspar, with lime, are subjected to a steaming operation.—A. B. S.

Process and apparatus for pulverising and treating ores, clag, and other mineral substances. U.S. Pat. 1,246,514. See 1.

IX.—BUILDING MATERIALS.

Cement clinker; Microscopical examination of —. T. Hattori. Kōgyō-Kwagaku-Zasshi (J. Chem. Ind., Tokyo), 1917, 20, 701—708.

SURFACES of cement clinker etched with water, or with dilute hydrochloric or hydrofluoric acid, show two predominating constituents, viz., alite, which is composed of crystals with square or hexagonal cross-section, and celite, the ground mass between these crystals, which is composed of two distinct substances, one white and the other grey. Eutectic structures may also be observed in the celite, especially in the case of clinker from stationary kilns. Alite is more readily attacked by water and dilute hydrochloric acid than the ground mass (celite), but offers greater resistance to dilute hydrofluoric acid. Some clinkers after being etched with dilute hydrofluoric acid show unattacked clusters of white granules, which, however, behave like alite when the specimens are etched with water or dilute hydrochloric acid, and have therefore been mistaken for a constituent of alite. For this reason hydrofluoric acid is preferable to hydrochloric acid or water as an etching reagent. The difference in the rate of cooling accounts for the presence of finer alite grains in clinker from a stationary kiln than in that from a rotary kiln. The alite grains in well-burnt clinker have sharp outlines, whereas in the case of insufficiently burnt clinker the forms are round and indefinite. The quantity of alite increases with the rise in the proportion of lime in the clinker. The quantity of alite is not the sole criterion of the quality of cement clinker, for its distribution must also be taken into account. In the case of good clinker there is uniform distribution, whilst poor clinker shows irregular distribution of groups of alite and celite. Hence chemical analysis does not afford sufficient data for judging as to the quality of cement clinker.—C. A. M.

Portland cement briquettes; Tensile strength test of neat —. T. Hattori. Kōgyō-Kwagaku-Zasshi (J. Chem. Ind., Tokyo), 1917, 20, 1018—1026.

OBJECTION is taken to the official Japanese method of testing the tensile strength of neat cement briquettes after 7 days instead of testing after 7 and 28 days the mortar prepared from it. Since the value of cement for mortar cannot be inferred from a test applied to the neat cement, and there

is no proportional relationship between the strength of a cement and of its mortar, it is suggested that for the future all tests should be applied to a mixture of cement and sand. The value of a cement depends upon the proportion of "flour" which it contains, for the grit (coarse particles) does not undergo hydration when mixed with water. By increasing the proportion of "flour" the tensile strength of neat cement briquettes is decreased, whilst that of the mortar briquettes is increased, and the reverse effects are produced by increasing the proportion of grit. Under the microscope hardened cement shows a mass of non-hydrated grains embedded in the hydrated mass, and as these grains are harder than the rest of the mass, the hardness of the section of neat cement when set is proportional to the percentage of grit therein. This would account for the low tensile strength of neat briquettes made from fine cement, whilst the proportion of sand which can be carried by fine cement causes it to yield a dense mortar which produces briquettes of high tensile strength.—C. A. M.

Cement floors subjected to injurious liquids; Protective treatments for —. W. P. Anderson. Met. and Chem. Eng., 1917, 17, 667—668.

TESTS were made on six different concretes prepared by the use, in varying proportions, of cement with sand or pebbles or both. Of the protectors tested nine were chemical hardeners (aluminium sulphate solutions varying in strength from 4% to 35%), three were oil hardeners, six were paints, two "blank" acid-proof coatings, and the others linseed oil with turpentine, a liquid preservative, paraffin wax, and a cement floor filler. The slabs were treated with acetic, sulphuric, nitric, and hydrochloric acids, sweet milk allowed to turn sour, and sugar solution. Some of the liquid hardeners afford good protection against dilute hydrochloric or acetic acid, and to a less extent against dilute nitric or sulphuric acid. Some paints and cement fillers, but not liquid hardeners, give good protection against strong hydrochloric acid. None of the protective agents tested was efficient with strong sulphuric acid. The milk tests were not complete but suggested the inadvisability of using paint as a protection against milk. Sugar was without effect on the concrete or the protective coverings.—B. V. S.

Asphalt industry; The colloidal state of matter in its relation to the —. C. Richardson. St. Paul (Minn.) Eng. Soc., May, 1917. Met. and Chem. Eng., 1917, 17, 650—653. (See also this J., 1917, 204.)

AN asphalt pavement may be regarded as a suspension of suitably graded sand and a finely-divided mineral filler in bitumen, which, from a physical point of view, may be treated as a liquid. In such a system an important factor is the surface energy, involving the relative surface, i.e., the smallness of grain, and the surface tension of the bitumen. This confirms the empirical conclusions from practical experience with pavements. An asphalt pavement is a colloidal solution in which the suspended matter, owing to the great viscosity of the continuous phase, may be of considerable coarseness. Clay can be introduced into asphalt by making a suspension in a liquid oily bitumen which can then be incorporated with a harder bitumen. The preliminary emulsification may be made in water which must then be removed by evaporation from the final product. Without some such treatment the clay grains cannot be wetted with bitumen owing probably to air films. Great differences were found in the colloidal capacity of bitumen samples when 1 part of colloidal clay was suspended in 2 parts of bitumen

and maintained at 325° F. (163° C.) for 24 hours. The percentage deposition of clay varied from nil in the case of Trinidad residual to 35.8% from a Mid-Continental semi-paraffin residual. Similar relations were found when the bitumens were diluted with carbon bisulphide. When solutions of varying concentration were made by dissolving Trinidad asphalt in benzol it was found that the capacity for carrying clay in suspension varied with the concentration and viscosity of the solution.—H. J. H.

PATENTS.

Alkali carbonate and hydraulic cement from alkali-ferous silicate minerals; Process of producing — E. W. Jungner, Kneippshaden, Sweden. Eng. Pat. 103,290, Dec. 8, 1916. (Appl. No. 17,708 of 1916.) Under Int. Conv., Jan. 7, 1916.

A FINELY-DIVIDED mixture of felspar or similar silicate, lime or other calcium compound, and carbon or suitable organic substance is heated in the presence of carbon dioxide or combustion gases or (if an electric furnace be employed) in the presence of an adequate supply of air, until complete volatilisation of the alkali is effected without melting the charge. The alkali is recovered, as carbonate, by conducting the gaseous products of the reaction into water and evaporating the resulting solution. The ratio of lime (CaO) to silica plus sesquioxides ($\text{SiO}_2 + \text{Al}_2\text{O}_3 + \text{Fe}_2\text{O}_3$) in the raw mixture should be at least 1.7 to 1 for the production of a satisfactory cement clinker.

—W. E. F. P.

Cementitious material; Calcareous — and process of making the same. W. E. Carson, Riverton, Va. U.S. Pat. 1,248,455, Dec. 4, 1917. Date of appl., Jan. 27, 1917.

THE plasticity of commercial fine ground cement is improved by the addition of a further quantity of the cement ground to a much greater degree of fineness.—W. E. F.

Concrete flooring and composition therefor. C. Ellis, Montclair, N.J., Assignor to Ellis-Foster Co. U.S. Pat. 1,246,827, Nov. 13, 1917. Date of appl., Apr. 26, 1917.

A CONCRETE floor is coated with a hydrocarbon solution of coumarone resin having a melting point of 55°–75° C. and substantially free from saponifiable substances. The resin gives a slightly tacky surface which is non-slipping but not seriously dust-absorbing.—W. E. F.

Wood; Substitute for — in building construction, and method of producing the same. W. H. Wheeler, New York. Eng. Pat. 111,686, Oct. 5, 1916. (Appl. No. 14,177 of 1916.)

A CEMENT containing about 60% of calcium oxide, such as Portland cement, is mixed with a binder such as sodium silicate and then with a fibrous material or filler such as asbestos or sawdust, so as to produce a plastic mass. Suggested proportions are filler 30%, cement 10 to 40%, and silicate 30 to 60%. The plastic mass is heated between former-plates or in moulds in a press as described in Eng. Pat. 1390 of 1912, until all moisture is removed. The cement makes the final product resistant to water and frost and enables it to be painted without special preparation. The silicate gives resilience to the product and facilitates its being worked with tools used for wood.—A. B. S.

Wood; Solution for preserving — F. Seiden-schnur, Charlottenburg, Germany. U.S. Pat. 1,248,022, Nov. 27, 1917. Date of appl., Feb. 3, 1912.

A SOLUTION for preserving wood is composed of water, an insoluble basic zinc compound, such as zinc hydroxide, and aluminium sulphate.—A. B. S.

Lumber; Process for rendering — resistant to sapstain. C. H. Teesdale, Madison, Wis. U.S. Pat. 1,248,711, Dec. 4, 1917. Date of appl., Apr. 9, 1917. (Dedicated to the public.)

LUMBER is rendered resistant to sap-stain—a discoloration caused by organisms—by covering it with a solution of sodium fluoride.—A. B. S.

X.—METALS; METALLURGY, INCLUDING ELECTRO-METALLURGY.

Steel plates; Action of caustic liquors on — C. E. Stromeyer, Annual Report of the Chief Engineer to the Manchester Steam Users' Assoc., 1916–1917. Chem. Trade J., Dec. 22, 1917, 533.

ATTEMPTS by Heyn and by Parr to reproduce the author's earlier results on this subject have been unsuccessful. The author records further recent observations. Evaporator tubes exposed to caustic soda liquors showed cracks where the steel had been stressed in tension but none where it had been under compression. This was confirmed by experiments in which pairs of rings were cut out of solid plate, one with taper outer edge and the other with taper inner edge so that it could be hammered over the former to leave the two concentric. The inner one was then in compression and the outer in tension. It was found that after exposure to caustic soda varying up to 4 months, the rings which had been in tension, whether annealed or not, developed numerous cracks on deformation, while those which had been in compression could be bent double without cracking. Further experiments in which it was intended to apply the stresses to steel in the form of a stressed spring proved abortive, because the metal on exposure to caustic soda lost its elasticity. The metal had not been maintained in the stressed condition during the test and afterwards it was found to have retained its ductility. Furthermore it had become extremely difficult to work either by sawing or milling. The loss of elasticity makes it difficult to carry out experiments under tension but in practice this may be maintained by steam pressure in boilers. The author approves of Parr's suggestion that the steel absorbs hydrogen when in contact with caustic soda and so acquires brittleness, but this is not yet clearly established.—H. J. H.

Electrolytic zinc; Future of — T. French. Amer. Electrochem. Soc., Oct., 1917. Met. and Chem. Eng., 1917, 17, 647–649.

THE author compares the prospects of retort smelting of zinc with those of electro-deposition in view of the rapid development of the latter in recent years. The yields obtained by electrolysis are very variable, but 90% is sometimes attained. Electro-zinc is usually a by-product of copper or lead smelting where the ores are zinciferous. In such cases the zinc is removed to facilitate the recovery of the principal metals and as the price of the zinc is not a prime consideration to the smelter, it will continue to compete more and more seriously with the retort product from high-grade zinc ores. The Wedge and Herreshoff furnaces are recommended for roasting complex zinc-lead ores, and a properly roasted product now presents no difficulties in the electrolytic process where current is cheap. The electrolytic process can be worked by less skilled and cheaper labour. Furthermore it is possible to recover precious and other metals at small cost. These aids to the financial economy are absent in the retort process. The presence of manganese is essential in the electrolytic process. In the bath it prevents sulphating and destruction of the anode. Manganese dioxide of marketable

quality is deposited at the anode at practically no cost. Large quantities of complex ores and zinc concentrates which are not available for the retort process are now sold very cheaply or tipped to waste. With cheap power, improvement of ore flotation methods, and electrolytic processes, the author looks forward to the exploitation of these and the ultimate displacement of the retort zinc.—H. J. H.

Brass pipe : Dezincification of —. E. B. Story. Met. and Chem. Eng., 1917, 17, 653—655.

Brass pipe used in water services has been found to deteriorate in a few years so as to become brittle and weak, and finally to fail completely. This is due to dezincification. Samples of the dezincified brass can be easily scraped off the affected portions of pipes and it has been found to contain up to 94.5% Cu when the original alloy was a 60:40 brass. The zones of varying decomposition in the metal can be brought out by etching with an ammoniacal solution of hydrogen peroxide. The author believes that potential differences are set up in brass as a result of strain, impurities, segregation, etc., and in presence of water some of the alloy goes into solution. When the copper ions come into contact with copper, deposition occurs, leaving the zinc in solution, so that ultimately a mass of loose copper accretions replaces the original alloy.—H. J. H.

Zinc : The sampling and assay of Chinese —. F. Browne. Chem. News, 1918, 117, 1—2.

Tin from the Yunnan mining district is refined in Hongkong in native foundries. When purchases are made, the Hongkong Government undertakes the analysis and certification of the metal. Every tenth slab is bored with a drilling machine, the borings being melted down under palm oil at a low temperature in an iron ladle. The cleaned sample ingot is filed, 1 gm. of the filings dissolved in hydrochloric acid, and the solution titrated with ferric chloride according to Parry's method, which has proved entirely trustworthy. The London Metal Exchange has decided that the Hongkong Government certificate shall be binding on all purchasers.—W. R. S.

Blast furnace slags : Viscosity of —. A. L. Fehd. Trans. Faraday Society, Dec., 1916. 33 pages. (See this J., 1916, 1237.)

BLAST-FURNACE processes must be worked at temperatures at which the slag is sufficiently fluid to permit an easy separation of metal but not so high as to cause excessive wear on the furnace linings. The slag has a desulphurising action in which diffusion probably plays an important part, and therefore low viscosity is desirable. Thus the temperature-viscosity relations of the slags in the liquid condition have a decisive influence on the fuel economy and working of the process. Fusibilities in terms of Seger cones, as hitherto employed in the study of slags, are of less importance, as they are not necessarily related to the viscosity of the slag in the liquid state. Furthermore, the conditions of the cone test lead to the oxidation of calcium sulphide to sulphate, which is not without influence on the fusibility of the slag. The viscosity apparatus previously described was modified to deal with slags up to 1600° C. The slag was melted in a graphite crucible which formed the outer rotating cylinder, and was attached to a vertical spindle which could be turned at a measurable speed. An inner cylinder of graphite was suspended so as to dip into the slag, the combination being enclosed by a vertical electric furnace, in which was maintained an atmosphere of nitrogen and carbon monoxide to

correspond with that of the blast-furnace. Temperatures were observed by a Holborn-Kurlbaum optical pyrometer sighted on the surface of the slag. The measurement of viscosity resolved itself into a determination of the speed of rotation necessary to be applied to the outer cylinder to produce a given torque on the inner one. Results are given of observations on eight commercial and two synthetic slags and an artificial diopside: the same results were found whether the temperature was rising or falling during the test. The curves of temperature-viscosity are apparently rectangular hyperbole, while those of the fluidity—i.e., the reciprocal of the viscosity—are rectilinear. At 1500° C. the average viscosity of the eight slags was 301 (water at 20°C. = 1), the extremes being 230 and 480. The cone softening temperature of the latter was found to be 1279° and of the former 1410°, thus emphasising the shortcomings of this method of studying slags. The high viscosity (480) was shown by a slag high in silica and low in alumina. The author suggests that this influence of silica is due to its molecular complexity which has been demonstrated at low temperatures by the researches of the Braggs and which probably persists in the liquid state.—H. J. H.

Hydrolysis of organic halides and the corrosion of metals. Doughty. See X.

PATENTS.

Furnace for steel melting : Electric —. S. Steinberg and I. Gramolin, Motowilichi, Russia. Eng. Pat. 111,679, June 27, 1916. (Appl. No. 9055 of 1916.)

IN an electric resistance furnace for the continuous treatment of steel, the carbon resistance rods extending across the heating chamber abut against block contacts, the latter being held by hollow, movable, metallic sleeves within which water is circulated. Spring and screw devices are provided for pressing the sleeves upon the block contacts and thus causing the latter to press upon and support the resistance rods.—W. E. F. P.

Steel : Process of treating — to prevent rusting. R. L. Gooding, Bridgetown, Barbados, U.S. Pat. 1,247,668, Nov. 27, 1917. Date of appl., Apr. 14, 1916.

THE steel is subjected to the action of strong phosphoric acid, and finely powdered iron is applied to the treated surface. The treatment is repeated at intervals and finally a thin coat of oil is applied.—T. H. B.

Furnace ; Metallurgical —. U. Wedge, Ardmore, Pa., U.S.A. Eng. Pat. 111,580, Jan. 25, 1917. (Appl. No. 1295 of 1917.)

IN a furnace consisting of a series of superposed hearths supported by rings attached to a central shaft, the hearths and rings are composed of separable segments which may be removed laterally through an opening in the outer wall which is normally closed by a movable section. The rabble blades have enlarged heads and project vertically through sockets in the horizontal supporting members, the upper part of each socket being enlarged for the reception of the blade head.—W. E. F. P.

Metals ; Method of hardening —. H. Scholey, London. Eng. Pat. 111,734, Dec. 22, 1916. (Appl. No. 18,380 of 1916.)

THE metal to be hardened is mounted as one of the electrodes, preferably the cathode, in an electrolytic bath (e.g., dilute sulphuric acid), and an electric current is passed through the liquid until the immersed portion of the metal has attained the necessary temperature. The current is then cut off and the metal allowed to cool while immersed.—W. E. F. P.

Metal-tempering compound. A. S. Carlson, Denver, Colo. U.S. Pat. 1,246,802, Nov. 13, 1917. Date of appl., Feb. 3, 1917.

A MIXTURE suitable for use in tempering metals is composed of approximately 10 galls. of kerosene and 1 gall. of creosote.—B. N.

Metal wire and strip: Electrolytic production of —. S. O. Cowper-Coles, Sunbury-on-Thames, Eng. Pat. 111,757, Jan. 31, 1917. (Appl. No. 1555 of 1917.)

THE metal is deposited on the disc-shaped, exposed surface of a cathode plate, the latter having a spiral engraved upon it and being provided with a central hole. The deposit is then detached from the plate and mounted on a spindle passed through the central hole, when, owing to the presence of weak lines occasioned by the spiral groove, the metal can be drawn off in the form of an approximately square wire or tape. The parts of the cathode plate upon which deposition is not required are provided with insulating plates or coated with insulating varnish.—W. E. F. P.

Electroplating. H. N. Gilbert, Brookline, Mass., Assignor to American Optical Co., Southbridge, Mass. U.S. Pat. 1,216,083, Nov. 13, 1917. Date of appl., Apr. 24, 1915.

A STATIONARY tank of non-conducting material is provided with a peripheral flange or shoulder near its upper end, a ring resting on the shoulder, and a perforated container of non-conducting material is fitted centrally within the ring. The container is suspended by a shoulder extending outwards and interlocking with the ring. A rotatable non-conducting stirrer, supported by a cap plate, is provided below with exposed cathode contacts, located within and near to the bottom of the perforated receptacle for making contact with the articles to be plated.—B. N.

[Copper] alloys; Process of making metallic —. H. Eldridge, New York. U.S. Pat. 1,246,571, Nov. 13, 1917. Date of appl., Dec. 22, 1916.

COPPER is alloyed with more fusible metals, e.g., zinc, lead, etc., by melting the copper in one vessel, and conveying the vapour of the alloying metal from a separate chamber so as to bring it into contact with the molten copper.—T. H. B.

Cadmium; Apparatus for removing — from zinc ores. C. P. Fiske, Palmerton, Pa., Assignor to The New Jersey Zinc Co., New York. U.S. Pat. 1,246,576, Nov. 13, 1917. Date of appl., Aug. 24, 1917.

THE ore charge is agitated in a rotary kiln and is heated by a current of heating gases (products of combustion), supplied directly to the interior of the kiln from a fire-box. A reducing atmosphere is maintained in the kiln by supplying a reducing gas, in regulated quantity, to the upper portion of the fire-box, so that it mingles with the products of combustion. Means are provided for recovering the cadmium expelled from the ore.—T. H. B.

Ore concentration process. W. A. Scott, Chicago, Ill. U.S. Pat. 1,246,665, Nov. 13, 1917. Date of appl., Aug. 17, 1917.

A MIXTURE of a vaporised "modifying agent" and air is introduced through a porous medium of fine texture into a body of ore pulp in the form of bubbles. The bubbles rise through the pulp and form a column of froth above the pulp, and the mineral matter which adheres to the bubbles is removed from the upper part of the column of froth.—T. H. B.

Sintering ores; Method and apparatus for —. J. Gayley, New York. U.S. Pat. 1,247,661, Nov. 27, 1917. Date of appl., Mar. 30, 1917.

A GRATE-BAR platform for a connected layer of

material is formed by a train of abutting cars; the cars are moved first under an igniter and then over a suction chamber. The cars are dropped at the end of their travel, without changing their upright position, thus breaking off a portion of the sintered material from the mass.—T. H. B.

Aluminium alloy. W. A. McAdams, Bayshore, N.Y. U.S. Pat. 1,247,977, Nov. 27, 1917. Date of appl., Apr. 5, 1914. Renewed May 1, 1917.

AN alloy of Al 100 parts by weight, Cu 17 parts, Zn 5 parts, Sb 1.5 parts, Ag 1 part.—T. H. B.

Etching metals; Method of —. J. L. Jones, Oakmont, Pa., Assignor to Westinghouse Electric and Manufacturing Co. U.S. Pat. 1,248,499, Dec. 4, 1917. Date of appl., June 11, 1915.

THE metal to be etched is immersed in a molten metal, e.g., zinc, of lower melting point, which is capable of alloying with it. The etched metal is withdrawn, adherent material is broken off, and the last traces removed by a suitable solvent, e.g., dilute sulphuric acid.—W. F. F.

Metals [e.g., copper]; Process of purifying —. I. Ladoff, Pittsburgh, Pa., Assignor to Westinghouse Electric and Manufacturing Co. U.S. Pat. 1,248,503, Dec. 4, 1917. Date of appl., May 11, 1914.

IN purifying molten metals, e.g., copper, an intimate mixture of copper, or a conglomerate containing copper, and titanous oxide, is added to the molten metal and acts as a gas-removing agent. The resulting slag is removed.—W. F. F.

Apparatus for separating substances of different specific gravities, such as fine coal or ores and the like. Eng. Pat. 111,826. See I.

Process and apparatus for pulverising and treating ores, clay, and other mineral substances. U.S. Pat. 1,246,514. See I.

Metallic yarn and method of treating same to facilitate weaving and for other purposes. U.S. Pat. 1,249,252. See V.

Testing or determining the hardness of metals and other substances. Eng. Pat. 108,460. See XXIII.

XI.—ELECTRO-CHEMISTRY.

PATENTS.

Furnace; Polypphase electric —. J. L. Dixon, Detroit, Mich. U.S. Pat. 1,248,632, Dec. 4, 1917. Date of appl., Jan. 20, 1917.

THE crucible of the furnace, containing the material to be treated, is provided with three electrodes connected to a two-phase three-wire system of current supply. The position of the common return electrode, or the one connected to the neutral point, is adjusted by two opposing electromagnets, so that its position is arranged in accordance with the proportion of the current carried relative to the total amount of current entering the furnace.—B. N.

Insulation; Flame-proof —. C. Ellis, Montclair, N.J., Assignor to New Jersey Testing Laboratories. U.S. Pats. 1,246,809 and 1,246,810, Nov. 13, 1917. Dates of appl., (A) July 26, 1915; renewed Sept. 14, 1917, (B) July 2, 1917.

(A) AN insulating composition, adapted for use in the coating of wire, is composed of a plastic insulating material incorporated with a non-inflammable chlorinated product of heavy petroleum, e.g., an "asphaltic oil," sufficient of the

latter being present to render the composition fire-proof. (B) A combustible insulating material is incorporated with a resin-like non-inflammable chlorinated wax, the material being sufficiently plastic to be used for the coating of wire.—B. N.

Insulating composition: Flame-proof—C. Ellis, Montclair, N.J. U.S. Pat. 1,248,638, Dec. 4, 1917. Date of appl., Aug. 5, 1915.

A READILY plastic and flexible insulating composition is composed of a combustible organic plastic insulating material incorporated with a mixture of non-inflammable chlorinated hydrocarbons of solvent naphtha. Sufficient of the latter must be present to render the composition flame-proof, without materially detracting from the flexibility of the insulated wire to which the composition is applied.—B. N.

Electrical-resistance material. C. Ruzicka, Gravesend. U.S. Pat. 1,246,165, Nov. 13, 1917. Date of appl., May 16, 1911.

SEE Eng. Pat. 11,975 of 1913; this J., 1911, 650.

[Electrolytic] process for the extraction of chlorine. U.S. Pat. 1,246,099. See VII.

Recovery of alkali [from silicates]. U.S. Pat. 1,246,619. See VII.

Depositing clay, plumbago and other like products on absorbent moulds. Manufacture of clay, plumbago, and other like articles by electrodeposition on metal moulds. Eng. Pats. 111,762 and 111,775. See VIII.

XII.—FATS; OILS; WAXES.

Globe-fish and angler-fish liver oils. M. Tsujimoto. Kōgyō-Kwagaku-Zasshi (J. Chem. Ind., Tokyo). 1917, 20, 709—711.

GLOBE-FISH liver oil (from *Spheroides porphyreus*) is a yellow liquid, which has a characteristic odour and deposits "stearine" at the ordinary temperature. It gives a red coloration, with purplish shade, on treatment with sulphuric acid. Angler-fish liver oil (*Lophomus setigerus*) is a yellowish-orange liquid which deposits "stearine," has a peculiar odour, and gives a reddish-purple coloration with sulphuric acid. These oils had the following characters:—

Oil from:	Sp. gr. at 15°/1° C.	Acid value.	Saponif. value.	Iodine value (Wijs).	Refractive index at 20° C.	Unsap. matter.	M. pt. of fatty acids.	Insol. bromide from fatty acids.	Bromine in insol. bromide.
Globe-fish liver	0.9269	0.88	182.2	159.8	1.4785	1.47	31—32	46.65	70.22
Angler-fish liver	0.9268	1.1	188.6	154.1	1.4790	1.00	32.5—34	44.13	70.65

The unsaponifiable matter from both oils melted at 100° C., and was free from the hydrocarbon, squalene, present in shark liver oil (see this J., 1916, 609, 1121).—C. A. M.

Fresh-water fish oils (carp, loach, and trout oils). M. Tsujimoto. Kōgyō-Kwagaku-Zasshi (J. Chem. Ind., Tokyo). 1917, 20, 711—720.

THE following characters were possessed by these oils:—

Oil from:	Sp. gr. at 15°/4° C.	Acid value.	Saponif. value.	Iodine value (Wijs).	Refractive index (20° C.)	M. pt. of fatty acids.	Insol. bromide from fatty acids.	Bromine in insol. bromide.
Carp (<i>Cyprinus carpio</i>)	0.9262	1.1	193.7	137.04	1.4756	20—30	28.29	63.77
Loach (<i>Misgurnus anguillicaudatus</i>) ..	0.9212	—	206.1	121.69	1.4740	31—32	25.45	68.01
Trout (a variety of <i>Oncorhynchus nerka</i>)	0.9305	1.8	196.7	179.98	1.4796	22	46.31	68.10
Trout (<i>Salmo iridens</i>)	0.9229	1.3	198.4	125.90	1.4736	33.5	22.97	68.63

The bromide from carp oil consists mainly of linolenic hexabromide with a small proportion of polybromides. The insoluble bromides from the fatty acids of the other oils behaved in the same way on heating as the bromides from marine animal oils, but contained a smaller proportion of bromine.—C. A. M.

Pulza-oil [curcas-oil] from the seeds of the physic-nut tree (*Jatropha curcas*); Industrial and economic use of—Investigation by the Colonial Garden of France. Rev. agric. et vétérin. de Madagascar. 1917, 2, [8], 37—38. Bull. Agric. Intell., 1917, 8, 1303—1304.

THE physic nut is at present obtained almost exclusively from the Cape Verde and Comoro Islands, and before the war about 500—600 tons was imported into France annually. Analysis of samples from Madagascar gave the following results:—1000 seeds weighed 535 grms.; the seeds consisted of 39.2% of shell and 60.8% of kernel, and the kernels contained 7% of moisture and 52% of oil. The oil-content of the whole seeds was 31.6%, corresponding to a commercial yield of 27—28%, since 4—8% of the oil would remain in the cakes. Pulza-oil (curcas-oil) is used in soap-making as a substitute for low-grade peanut oil, and it might also be employed in stearin factories. Its low acidity should render possible its application as a lubricant. It may also be used as a purified oil. Before the war the current price of physic-nut seeds was 13s.—20s., but at the present time they should command 40s. per 100 kilos, net at Marseilles.—J. H. L.

Oil of Cáy-doc (*Garcinia tonkinensis*). F. Heim. Bull. économique de l'Indochine, 1917, 20, [123] (new series), 135—139. Bull. Agric. Intell., 1917, 8, 1304—1305.

THE seeds of the Cáy-doc or Cáy-gioc, a tree of the family *Clausiaceae*, have long been the object of an important trade in Tonkin, and are used for the extraction of a burning oil. The oil is a mixture of true fats and oleo-resin containing a small proportion of ethereal oil of agreeable odour. The oleo-resin is probably of no commercial value, as it does not solidify on desiccation or oxidation. The oil has the following constants:—acid value, 93; saponif. value, 198; iodine value, 67.14;

Reichert value, 0.53. Saponified with caustic soda, it furnishes about 90% of fatty acids, brown in colour, melting at 22° C., and composed of a mixture of solid fatty acids (mainly stearic and palmitic) and oleic acid. It is easily saponified and yields a brown coloured soap which, in appearance and to some extent in odour, resembles palm-oil soap. The proportion of essential oil is small (4.58%), and the presence of resin is not harmful but promotes the formation of lather, even in water

containing calcium sulphate. *Garcinia lonkinensis* is grown in Tonkin; it matures in 8–10 years and would yield a full crop of seed only after 25 years. The annual crop of seed per tree should be worth a Tonkin piastre (about 2 shillings).

—J. H. L.

Oils and fats; Valenta number as a discriminating test for —. P. J. Fryer and F. E. Weston. Analyst, 1918, 43, 3–20.

THE turbidity temperatures obtained in the ordinary method of applying the Valenta test are greatly affected by the presence of water or free fatty acids in the oils. Acetic acid is extremely hygroscopic and the Valenta results are affected by leaving the bottle unstoppered for a short time before using the acid. In the case of almond oil containing 1.1% of free acids the Valenta value increased about 1.5° C. for each 0.1% of moisture absorbed. Absolute alcohol is less affected by the absorption of moisture, the Valenta value being increased by about 0.75° C. for each 1.1% of added water. A mixture in equal vols. of 90 to 92% alcohol and amyl alcohol absorbs much less water than either acetic acid or alcohol. Thus in the case of the same almond oil the Valenta values before and after exposure of the reagent for 16 hours in an unstoppered bottle were 69.2° and 69.8° C. respectively. To obviate the effect of water in the oil the heated sample may be filtered through dry cotton-wool. For standardising the solvent the use of pure almond oil with an iodine value below 100 is suggested, and the solvent is diluted so as to give a turbidity temperature of about 70° C. with this oil. About 0.11% of water corresponds with a rise of 1° C. in the Valenta figure. The effect of free acids in the oil or fat is to cause a fall in the turbidity temperature, the amount of depression caused by each 1% of acidity (as oleic acid) being as follows:—Marine oils, 1.95°; drying oils, 2.05°; semi-drying oils, 2.03°; non-drying, 2.07°; rape type of oils, 1.61°; vegetable fats (except coconut oil), 1.72°; coconut group, 2.01°; animal fats (except butter fat), 2.13°; and butter and milk fats, 1.54° C. Heating the oil before applying the test has a pronounced influence on the results when acetic acid is used as solvent, but has only a slight effect in the case of the amyl-ethyl alcohol solvent. Slight oxidation of an oil does not materially affect the result, but pronounced oxidation causes pronounced lowering of the temperature. After determining the value of an unknown oil the tube is washed out with hot alcohol, the acidity determined with $N/10$ alkali solution, and the appropriate correction for the class of oil applied. In the case of acetic acid as solvent the standard temperature with neutral almond oil is fixed at 80° C., and the results may be expressed either as $V = t + (80 - t_1)$, where t is observed temperature and t_1 the temperature of the same acid with the standard oil; or as $X = \frac{V \times 10}{80}$, where V represents the true Valenta figure. By the use of the ethyl-amyl alcohol solvent it is possible to distinguish between animal and vegetable waxes (other than insect wax) and mineral waxes. For example the following values were obtained:—Carnauba wax, 82°; candelilla wax, 63°; beeswax, 76°; spermaceti, 44°; insect wax, insoluble; montan refined wax, 70°; ozokerite, insoluble; paraffin wax, insoluble; beeswax + 10% ceresin, 82°; candelilla wax + 10% paraffin wax, 72°; and candelilla wax + 33% paraffin wax, 83° C.—C. A. M.

Fats; Relationship between the chemical constitution and refractive index of —. C. Chénveau. Comptes rend., 1917, 165, 1060–1062.

ASSUMING a fat in the liquid condition to consist of a solution of one or more solid glycerides and one or more liquid glycerides, the law of solutions

would hold good, and the refractive index of the fat could be calculated from the percentage proportions and refractive indices of the component glycerides by means of the formula:—

$$\Sigma p \frac{n-1}{d} + \Sigma p^1 \frac{n^1-1}{d^1} = 100 \frac{N-1}{D}$$

Solid glycerides Liquid glycerides Fat

Again, assuming the iodine value, I , to afford a measure of the unsaturated (liquid) glycerides, then $p^1 = KI$, and the law of solution may be expressed as:—

$$N-1 = A + BI,$$

in which A and B are two coefficients expressing the relationship between the refractive index and the iodine value of a fat. In the case of non-drying oils the line expressing this relationship graphically is more inclined towards the axis of the abscissæ than in the case of drying and semi-drying oils, but as the temperature rises the two lines tend to become identical.—C. A. M.

Utilisation of waste tomato seeds and skins. Rabak. See XIXA.

PATENTS.

"Foots" or soap-stock; Process whereby neutral oils can be profitably recovered from —. E. E. Ayres, jun., Chester, Pa., Assignor to The Sharples Specialty Co., West Chester, Pa. U.S. Pat. 1,247,782, Nov. 27, 1917. Date of appl., May 21, 1917.

THE "foots" is treated with an amount of water equal to at least half its weight together with a reagent capable of reducing the stability of the emulsion. The whole is then heated, allowed to settle, the bulk of the soap solution separated from the bulk of the oil, the latter centrifuged, and the separated emulsified oil treated with salt. The oil is then separated from the salted product by gravity.—A. de W.

Saponifiable oils; Process of refining —. C. Baskerville, New York, Assignor to The Baskerville Processes Corporation. U.S. Pat. 1,246,379, Nov. 13, 1917. Date of appl., Aug. 2, 1915.

XIII.—PAINTS; PIGMENTS; VARNISHES; RESINS.

Colour-technology; The physical basis of —. M. Luckiesh. Met. and Chem. Eng., 1917, 17, 631–637.

THE author deals in a general way with the value of an analytical method of considering technical problems in colour. (For a detailed statement of apparatus, methods, and data, see "Colour and its applications," 1915, D. Van Nostrand Co., and for additional spectro-photometric data, see Luckiesh, J. Franklin Inst., 1917, 184, 73, and 227.) The first factor to consider is the colour value of the illuminant used which should be considered as almost a part of the coloured medium. Curves showing the spectral reflection factors of ultra-marine blue and its spectral luminosity curves for skylight, sunlight, and a tungsten vacuum lamp illustrate the point. There are three main methods in use for the analysis of colour. The most analytical is by means of the spectro-photometer, which determines the reflection or transmission factors of the colour for all wave lengths of the

visible spectrum. By combining these factors with the corresponding spectral values of the illuminant and the visibilities of radiation, the spectral luminosity curve is obtained. A series of curves for chrome yellow illustrate this method. The monochromatic colorimeter expresses the value of a colour in terms of its dominant hue, its percentage of saturation (= unity minus percentage white), and a transmission or reflection factor; chrome yellow has a dominant hue, 0.583μ , a saturation of 75%, or 25% white, and a reflection factor, as determined by the spectro-photometer analysis, of 82%. The trichromatic colorimeter is based on the Young-Helmholtz theory; chrome yellow by this method is expressed as red 58, green 37, blue 5, as compared with a white standard of 33.3 for each component. In considering pigments the reflection factor curves are given for a number of dry powders. Further sections deal with dyes and coloured glasses and with the laws of combination and of variation of colour with thickness for both of these. Numerous suggestions are made throughout the paper as to applications of the results already obtained and as to further information required.—B. V. S.

PATENTS.

Paint or composition and process of manufacturing the same. G. Peacock, Gravesend, Eng. Pat. 111,507, Nov. 24, 1916. (Appl. No. 16,853 of 1916.)

A COMPOSITION for use in screening glass, etc., is composed of size (7 lb.), dark green or other dry pigment (5 lb.), whitening (2 lb.), and potassium bichromate ($1\frac{1}{4}$ oz.); it is prepared by stirring the pigment and whitening into the melted size, adding the bichromate dissolved in water, and thoroughly mixing.—W. E. F. P.

Paint. Submarine paint. L. S. Tarrant, Hawera, New Zealand. U.S. Pats. (A) 1,247,900 and (B) 1,247,901, Nov. 27, 1917. Date of appl., Jan. 12, 1916.

(A) A PAINT composition comprises defibrinated animal blood, raw linseed oil, driers, and pigment. (B) A submarine paint comprises defibrinated animal blood, linseed oil, resin, and pigment.

—A. DE W.

Pigment; Process of making—and product thereof. P. J. Oakes, New York. U.S. Pat. 1,248,285, Nov. 27, 1917. Date of appl., Dec. 10, 1913.

A HOMOGENEOUS amorphous neutral pigment is obtained by precipitating an acid solution containing a colour lake, e.g., from logwood, including an oxidised colour principle, with an alkaline solution of a resin. The mass is then boiled, and the pigment separated and dried.—A. DE W.

Lead sulphate pigment; Process of making—. R. E. Kroher, Collinsville, Ill., Assignor to St. Louis Smelting and Refining Co., St. Louis, Mo. U.S. Pat. 1,248,591, Dec. 4, 1917. Date of appl., Apr. 23, 1917.

WHITE lead pigment is made by heating a mixture of lead-bearing materials, metallic lead in the form of flakes, a flux, and fuel, in a blast furnace. The vapour produced is condensed and the pig lead is tapped off and poured into a stream of water to flake it for subsequent use.—W. F. F.

Resin and like material; Apparatus for melting—and filling receptacles therewith. J. W. Westwood, sen., and J. W. Westwood, jun., Birmingham. Eng. Pat. 111,905, Dec. 14, 1916. (Appl. No. 17,981 of 1916.)

AN apparatus for melting resin and discharging it into receptacles, specially adapted for filling shrapnel shells, consists of a melting tank heated by superheated water, and a support for

the tank to which is fitted a filling platform adjustable vertically. The melting tank is fitted with one or more discharge taps, of which the portion bearing the valve projects into the tank.—A. DE W.

Hydrogenated resin; Process of making—. C. Ellis, Montclair, N.J. U.S. Pat. 1,249,050, Dec. 4, 1917. Date of appl., Feb. 2, 1916.

THE tackiness of resin is reduced by treating a solution of the same in a hydrocarbon inert to hydrogen, with arsenic-free hydrogen at about 10 lb. pressure in the presence of a nickel catalyst at a temperature above that of the decomposition of nickel abietate.—A. DE W.

Impregnating process. A. L. Brown, Wilkinsburg, Pa., Assignor to Westinghouse Electric and Manufacturing Co. U.S. Pat. 1,248,447, Dec. 4, 1917. Date of appl., Dec. 10, 1914.

ABSORBENT material is impregnated by successively applying to it a polymerisable liquid, such as a raw drying oil, and a polymerising agent such as a drier.—A. DE W.

Manufacture of colouring matters [from residues from manufacture of trinitrotoluene]. Eng. Pat. 111,738. Sec IV.

XIV.—INDIA-RUBBER; GUTTA-PERCHA.

PATENTS.

Rubber and other products; Manufacture of— from latices and the treatment of raw, inferior or scrap rubbers and rubber gums. R. B. Ransford, London. From C. A. Heken and St. V. B. Down, Singapore. Eng. Pat. 111,906, Dec. 14, 1916. (Appl. No. 17,991 of 1916.)

LATICES, inferior or imperfectly coagulated rubbers, raw rubbers, tacky rubbers, etc., are treated in the cold with a solution of asphalt, bitumen, pitch, tar, or similar material in a suitable solvent, by which treatment the rubber is rendered harder and stronger, and impervious to bacteria or moulds. In treating latices the addition of the asphalt solution is followed by treatment with a suitable coagulant, whereas with the various grades of rubber the application of the solution is merely superficial. In either case the treatment may be combined with the processes described in Eng. Pats. 8487 of 1915 and 110,566 and 111,907 (this J., 1916, 854; 1917, 1280, and following).—D. F. T.

Rubbers; Process for purifying raw inferior or scrap—. R. B. Ransford, London. From C. A. Heken and St. V. B. Down, Singapore. Eng. Pat. 111,907, Dec. 14, 1916. (Appl. No. 17,992 of 1916.)

INFERIOR, dirty, or imperfectly cured rubbers or scrap rubbers are treated with an aqueous solution containing 1% to 3% of a salt such as a sulphite, bisulphite, or hydrosulphite, which by the addition of a small amount of sulphuric acid can be made to yield sulphur dioxide. The rubber, thus treated, is preferably soaked or sprayed subsequently with a mixture of methylated spirit and benzine, the purified rubber then being ready for blocking or crêping and drying.—D. F. T.

Vulcanised rubber composition and method of preparing same. H. A. Gardner, Washington, D.C. U.S. Pat. 1,247,257, Nov. 20, 1917. Date of appl., July 31, 1917.

A COMPOUND of high tensile strength and toughness is obtained by incorporating a finely divided insoluble zirconium compound with rubber and then vulcanising.—B. V. S.

Vulcanisable plastics; Process for regulating treatment of —. E. E. A. G. Meyer, Detroit, Mich., Assignor to Morgan and Wright. U.S. Pat. 1,217,983, Nov. 27, 1917. Date of appl. Jan. 31, 1917.

THE plastic is placed in a mould and a heating medium at a vulcanising temperature is applied in such a way that the rate of expansion of the plastic in the mould may be regulated.—D. F. T.

Cumaron-rubber product; Vulcanised — and process of making same. A. A. Wells, Caldwell, N.J., Assignor to Ellis-Foster Co. U.S. Pat. 1,218,226, Nov. 27, 1917. Date of appl. Apr. 25, 1917.

A MIXING containing natural and reclaimed rubber together with coumarone-resin and various fillers, is vulcanised.—D. F. T.

Caoutchouc; Treating products resembling —. E. Münch, Assignor to Badische Anilin und Soda Fabrik, Ludwigshafen, Germany. U.S. Pat. 1,248,888, Dec. 4, 1917. Date of appl. Feb. 26, 1914.

RUBBER-LIKE polymerisation products of butadiene are heated with a mixture of solid caustic alkali and an alkali carbonate, the material being thereby improved; it may be subsequently vulcanised. (See also Fr. Pat. 463,437 of 1913; this J., 1914, 365.)—D. F. T.

Vulcanising rubber; Process for — and products obtained thereby. I. Ostromislenski, Petrograd, Assignor to New York Belting and Packing Co., New York. U.S. Pats. (A) 1,249,180 and (B) 1,249,181, Dec. 4, 1917. Dates of appl., July 28 and Nov. 24, 1916.

(A) RUBBER is vulcanised by mixing with a compound containing nitrogen and oxygen, *e.g.*, trinitrobenzene, which is capable of yielding oxygen to the rubber; on heating, the oxygen induces vulcanisation. (B) Vulcanisation of rubber is effected by the action of a peroxy-compound such as benzoyl peroxide.—D. F. T.

Vulcanising rubber with selenium or its compounds; Process for —. C. R. Boggs, Arlington Heights, Mass., Assignor to Simplex Wire and Cable Co., Boston, Mass. U.S. Pat. 1,249,272, Dec. 4, 1917. Date of appl., Mar. 16, 1916.

A QUANTITY of selenium or selenium compound is incorporated with the rubber, together with an artificial accelerator such as β -naphthylamine, and the mixture is then vulcanised by heat.—D. F. T.

Rubber; Process for the complete removal of — from the canvas of worn-out pneumatic tyres. H. Debauge, Paris. U.S. Pat. 1,248,463, Dec. 4, 1917. Date of appl., July 20, 1914.

XV.—LEATHER; BONE; HORN; GLUE.

Sulphide; Estimation of — in [tannery] lime liquors. Part 2. H. G. Bennett, J. Soc. Leather Trades Chem., 1917, 2—S. J. Amer. Leather Chem. Assoc., 1917, 12, 626—632.

IT is maintained against McCandlish and Wilson that a certain amount of ammonia is necessary in the zinc sulphate and ammonium chloride reagent used for titrating sodium sulphide in lime liquors. Precipitation of zinc hydroxide and escape of hydrogen sulphide are thereby prevented, and though an error is caused by the retention of zinc-ammonium ions in solution, it is negligible in the titration of ordinary lime liquors if the *N*/10 zinc sulphate solution contains 5% of ammonium chloride and 25 c.c. per litre of concentrated ammonia. Experiments are described in support of the above.—F. C. T.

Sulphide; Estimation of — in [tannery] lime liquors. D. McCandlish and J. A. Wilson. J. Amer. Leather Chem. Assoc., 1917, 12, 633—634.

REPETITIONS of Bennett's experiments (see preceding abstract) do not support his contentions. A pure lime-sulphide solution of which 50 c.c. required about 6 c.c. of reagent, was titrated with *N*/10 solutions of zinc sulphate containing 5% of ammonium chloride and amounts of ammonia varying from 0 to 30 c.c. of concentrated ammonia solution per litre. In no case (even in the absence of ammonia) was there any odour of hydrogen sulphide. On the other hand, with a liquor containing 0.5% of sodium sulphide there was a distinct evolution of the gas.—F. C. T.

Preparation of lannic acid, gallic acid, and pyrogallol. Milo. See XX.

PATENT.

Leather; Process of producing artificial —. C. E. Arnold, Assignor to E. I. du Pont de Nemours Powder Co., Wilmington, Del. U.S. Pat. 1,247,610, Nov. 27, 1917. Date of appl., Sept. 3, 1914. Renewed May 16, 1917.

A COATING of a nitrocellulose cementing composition is applied to a fabric and a coating of a nitrocellulose plastic is then applied by means of calender rolls before the first coating has dried.

XVI.—SOILS; FERTILISERS.

Rarer elements in soils and plants; Relation of some of the —. W. O. Robinson, L. A. Steinkoenig, and C. F. Miller. U.S. Dept. of Agriculture, Bull. 600, 1917, 25 pages.

THE results of the analyses of the ashes of a large number of plants, bushes, and trees showed that lithium was present in all the plants examined. Rubidium was present in most cases and in larger quantities than the other rare alkalis, cesium being present in only a few cases. These two elements are apparently absorbed by the plant when present in the soil solution, the amount absorbed increasing with the amount present in the soil. Chromium and vanadium were only found occasionally and then only in traces, and there was no indication that vanadium could replace phosphorus in its functions in the plant. Molybdenum was never detected in the plants. Barium and strontium were found in all cases and titanium was invariably present though in very small amounts. There is no indication that these rare elements need be considered in fertilising practice. In an appendix a full description is given of an electric furnace, with an automatic regulator, suitable for incinerating plants at a comparatively low temperature (525°C.) in order to avoid loss of alkali by volatilisation.—W. G.

Peaty soils; Hydrogen ion concentration of extracts of — and of plants which form peat and humus. H. Kappen and M. Zapfe. Landw. Versuchs-Stat., 1917, 90, 321—374.

ALTHOUGH aqueous extracts of peaty soils have a marked conductivity and contain organic and inorganic substances, the hydrogen ion concentration only slightly exceeds that corresponding with the neutral point, so that soluble acids can be present in traces only. The power of these soils to decompose neutral salts is probably due to an exchange of ions rather than the liberation of free acid. In the case of peat-forming plants, the hydrogen ion concentration of their aqueous extracts is usually higher than corresponds with the neutral point, and the true acidity is marked.

—W. P. S.

Plants; Action of dicyanodiamide on the growth of —. T. Pfeiffer and W. Simmermacher. Landw. Versuchs-Stat., 1917, 90, 415—430.

WHILST the germination of oats is not affected by the presence of considerable quantities of dicyanodiamide in the soil, the growth of the plants and the yield of grain are affected injuriously. The quantity of dicyanodiamide usually found in nitrolim (crude calcium cyanamide) is, however, quite small, but the substance should be considered as an impurity which may possibly have an injurious effect on the crops.—W. P. S.

PATENTS.

Calcium cyanamide; Manufacture of crude —. Elektrizitätswerk Lonza, Gampel and Basle, Switzerland. Eng. Pat. 107,751, Dec. 21, 1916. (Appl. No. 18,326 of 1916.) Under Int. Conv., July 6, 1916.

IN the manufacture of crude calcium cyanamide from calcium carbide, an inclined, cylindrical, rotary furnace is employed through which nitrogen is circulated, the temperature of reaction being regulated by heating or cooling the gas as required. The furnace has an extension at each end, and forms part of a closed system provided with a fan and with separate heating, cooling, and dust chambers. The extension at the lower end, through which the nitrogen is admitted, forms a cooling chamber for the crude cyanamide and is connected with a sealed discharge receptacle. The nitrogen exit pipe of the furnace is disposed co-axially within the upper extension, through which the carbide is fed, the annular space between the two thus forming a chamber which is not traversed by the circulating gas, so that excessive "dusting" of the charge is avoided.—W. E. F. P.

Fertiliser; Process of making —. J. E. Zilk, Assignor to Odorless Fertilizer Manufacturing Co., Pittsburgh, Pa. U.S. Pat. 1,247,059, Nov. 20, 1917. Date of appl., Feb. 10, 1917.

A MIXTURE of phosphate rock, 2000 lb., coke, 200 to 300 lb., powdered limestone, 200 to 300 lb., and nitre cake, 400 lb., is heated to incipient clinkering.—B. V. S.

Process of recovering ammonia and potassium-containing material from tobacco waste. U.S. Pat. 1,247,060. See VII.

XVII.—SUGARS; STARCHES; GUMS.

Inulin; Comparative examination of pure and commercial —. J. Wolff and B. Gestin. Ann. Chim. Analyt., 1917, 22, 211—212.

FERMENTATION experiments with a Burgundy yeast, Annamite yeast (see Will, this J., 1913, 1123), and *S. Pombé*, showed that contrary to the statements of some authors, pure inulin is quite unfermentable. A sample of commercial inulin prepared by Dragendorff's method was attacked strongly by *S. Pombé* and to a smaller extent by the other yeasts. It is concluded that inulin prepared by Dragendorff's method contains inulides (see this J., 1917, 1286).—J. H. L.

Distillation of cellulose and starch in vacuo. Pietet and Sarasin. See IIb.

Polarimetric determination of starch in grain, milling products, etc. Hals and Hegggenhougen. See XIXa.

Syrup evaporator. P. A. Yoder, Washington, D.C. U.S. Pat. 1,248,237, Nov. 27, 1917. Date of appl., Apr. 3, 1916. (Dedicated to the public.)

A SYRUP evaporator comprises a vat provided

with suitable supports and having an impervious floor consisting of a number of tubes fastened securely together, heads secured to the open ends of the tubes, baffle-plates adjusted in the vat, and troughs arranged along the sides thereof, the tubes and heads providing a passage-way for heating medium for heating the syrup.—J. F. B.

Vegetable glue or adhesive [from starch]. R. W. Tunnell, Philadelphia, Pa. U.S. Pat. 1,248,039, Nov. 27, 1917. Date of appl., May 3, 1917.

HYDROLYSED starch or a derivative is treated with an alkali aluminate or with alum in excess of caustic soda to form sodium aluminat in the hydrolysed starch.—J. F. B.

XVIII.—FERMENTATION INDUSTRIES.

Yeast; Contribution to the knowledge of —. J. J. Van Hest. Woch. Brau., 1917, 34, 327—328, 341—343. (See also this J., 1901, 30, 831, 915.)

COMPARATIVE laboratory fermentations of sterilised malt wort by a mixture of four top-fermentation yeasts were carried out under different conditions, viz., (A) with continuous rousing by means of a current of sterile air, (B) with the wort covered by a layer of olive oil to exclude air, and (C) under ordinary conditions. In each case 4 c.c. of pressed yeast per litre was used, and the fermentations were carried out to completion at 17.5° C. The wort nitrogen assimilated by the yeast was 0.4, 0.28, and 0.36 gm. per litre in the respective cases, and the amounts of yeast produced were respectively 16.4, 8.2, and 8.8 times that used for seeding. The crop produced by aeration was thus much larger than the others but its nitrogen content was much lower; the individual cells were also about 25% smaller, so that the aerated yeast contained only about half as much nitrogen per cell as that formed under ordinary conditions (C). The nitrogen-content of the aerated yeast, referred to dry substance, was 6.3%, practically the same as that of colonies grown under aerobic conditions on the surface of wort-gelatin (the seeding of the latter having been effected by pouring a yeast suspension over its surface). As the multiplication of the yeast in the colonies was incomparably greater than in the wort, the author considers that 6% represents about the minimum nitrogen-content possible for the yeast. The maximum possible nitrogen-content is probably about 10%, this being the value for the seed-yeast and also for the crop formed under normal conditions (C). To study the effect of prolonged anaerobic growth on the yeast, 13 successive fermentations were carried out under the same conditions as in (B), each fresh lot of wort being seeded with a small quantity of sedimentary yeast from the preceding one and fermented for 5 days at 17.5° C. The results are given in tables. The action of the yeast was irregular, but on the whole the later fermentations proceeded as far as the earlier ones. However, the yeast, even from the earlier fermentations, contained a high proportion of dead cells and abnormal forms indicating degeneration. The author concludes that it would be inadvisable to use a top-fermentation yeast in brewing, after even one fermentation under anaerobic conditions. Copious aeration promotes the biological activities of yeast at the expense of fermentative action, whilst lack of air, or the use of large proportions of seed yeast, promotes fermentative activity at the expense of reproduction.—J. H. L.

Autoamylases; Some nitrogenous —. E. W. Rockwood. J. Amer. Chem. Soc., 1917, 39, 2745—2752.

α -AMINO-ACIDS, whether aliphatic or cyclic,

increase the hydrolytic activity of saliva on starch and are called auxoamylases. In the cyclic compounds the effect is the same whether the amino group is in the benzene ring or the side chain, and is independent of its position in the ring. Amides are not auxoamylases and the introduction of an amino group into the carboxyl group destroys the effect of an amino group already present elsewhere in the molecule. Imides and aminosulphonic acids are not auxoamylases, but the replacement of a hydrogen in the amino group of an amino-acid by an acyl group does not destroy its stimulating effect. Proteins act as auxoamylases, their action being increased as the number of free amino groups is increased by the hydrolysis of the protein. Similar results are obtained with pancreatic amylase as with the ptyalin.—W. G.

Bran as a new raw material for cereal beverages.

R. Wahl. Amer. Brewers' Review, 1917, 31, 323—324.

In experiments at the Wahl-Henius Institute it was found that, contrary to the opinion of many authorities, the aleurone layer of seeds generally, including those of all the cereals examined, contains fairly large quantities of diastase. Wheat-bran, for example, will under suitable conditions convert 5—8 times its weight of gelatinised starch, and as it is rich in proteins and mineral constituents it is proposed to use it, together with starchy materials, for the manufacture of alcoholic beverages and for kindred purposes (see Eng. Pat. 101,406; this J., 1917, 936, and U.S. Pat. 1,249,259, p. 69A). The nitrogenous and mineral constituents may be rendered soluble by mashing at a suitable temperature in presence of a sufficiently high acidity produced either by addition of lactic acid or by development of lactic bacteria. Using wheat bran and gelatinised cereal starch, and modifying somewhat the ordinary methods of operation, it was found possible to produce pale and dark bottom-fermentation beers, products of the character of ales and stouts, and also syrups resembling malt extracts and having a stimulating action on yeast in baking. The diastase of bran (translocation diastase) is believed to have a somewhat lower optimum temperature of saccharification (45°—50° C.) than that of malt diastase (50°—60° C.), and in using the former it is possible so to control the mashing process as to produce a wort containing less sugar than ordinary brewers' wort.—J. H. L.

Alcoholic ferments; Study of — [in apple must].

E. Kayser. Comptes rend., 1917, 165, 1020—1022. (See also this J., 1917, 608, 902.)

THE author investigated the products of the slow fermentation of sterilised apple must by a wine yeast, a cider yeast, and a perry yeast, and also in each case the effect of adding ammonium phosphate, equivalent to 1 gm. of nitrogen per litre, before fermentation. In each case the must (of sugar-content 11.1% and acidity 0.616% as malic acid), contained in a long-necked flask filled to the neck so as to expose only a very small surface to the air, was inoculated with a drop of yeast culture, and kept at 5—18° C. for a year, after which analyses were made of the fermented must and the spirit (*eau-de-vie*) obtained from it. The results are given in tables. In the musts which had not been treated with phosphate, the alcohol-content ranged from 6.85 to 6.93%, the total acidity (as malic acid) from 5.84 to 7 grms. per litre, and the volatile acidity (in terms of acetic acid), from 0.05 gm. (for the perry yeast) to 0.368 gm. (for the cider yeast) per litre. The volatile acidity consisted of acetic and butyric acids with traces of formic acid, and was in most cases lowered as the result of the addition of

phosphate, referred to above. The distillates from the musts not treated with phosphate contained in all cases large amounts of aldehydes (323—394 mgrms. per 100 c.c. of alcohol) and higher alcohols (from 167 mgrms. for the cider yeast, to 364 mgrms. for the wine yeast); the phosphate treatment reduced these amounts considerably, especially in the case of the wine yeast. The ester-content of the distillates was in all cases relatively small, ranging from 43 to 67 mgrms. per 100 c.c. of alcohol.—J. H. L.

Wines; Constitution of the non-volatile acidity of sound and sick —. J. Laborde. Comptes rend., 1917, 165, 1017—1020. (See also this J., 1918, 36 A.)

THE author divides the non-volatile acidity into two parts: that soluble in a mixture of alcohol and ether, due to lactic, succinic, malic, and citric acids, and that insoluble, due mainly to acid potassium tartrate. Analysing six French and Algerian wines, he was able to account for nearly the whole of the non-volatile acidity by determining the amounts of the various acids present and subtracting the alkalinity of the ash, everything being expressed in terms of sulphuric acid. The actual amounts of the various acids found were, in grms. per litre: lactic acid 0.84—1.90, succinic acid 0.61—0.75, malic acid 0.45—4.26, tartaric acid 1.66—3.47, and citric acid (in the two Algerian wines, to which it had probably been added) 1.10—1.66. Sound wines may thus contain considerable amounts of lactic acid. Analyses of some sick wines are also given. In one sample which underwent de-acidification the malic acid diminished from 4.99 to 1.20 grms. per litre in six months, whilst the lactic acid increased from 1.05 to 2.74 grms. and the tartaric acid remained constant. Two wines suffering from *tourne* were found to contain no tartaric acid, 0.36—0.67 gm. of malic acid, and 2.24—2.40 grms. of lactic acid per litre, and the volatile acidity was high. Two bitter wines contained 1.14—1.97 grms. of tartaric acid, 1.08—1.20 grms. of malic acid, and 3.06—3.68 grms. of lactic acid. In all these wines the succinic acid was remarkably constant at about 0.6—0.8 gm. per litre. The amounts of malic and tartaric acids vary according to the origin of a wine and the influence of filiform organisms such as those which produce *tourne* and bitterness; the former acid appears to be more readily decomposed than the latter by these organisms.—J. H. L.

Wines; Bitter —. E. Kayser. Rev. Viticulture, 1917, 47, 70—75. Bull. Agric. Intell., 1917, 8, 1295—1297.

ANALYSIS of three French wines suffering in different degrees from "bitterness" indicates that the disease is associated with a reduction in the content of fixed acids and of total tartaric acid but not in that of volatile acids; the amounts of both volatile and non-volatile esters also increase whilst the glycerol-content diminishes (cp. Voisinot, this J., 1910, 1126; 1911, 1026; 1913, 503, 620). The volatile acids and esters were investigated by the method of Duclaux; acetic and butyric acids were found to be present, and in one case formic acid. The two samples most strongly attacked contained 0.0267 and 0.0187 gm. of ammonia per litre, as compared with 0.006 gm. in the third sample which was only slightly bitter.—J. H. L.

Saké; Pasteurisation (hiire) of — by electric heating. T. Tadokoro, F. Ibuki, and S. Iguchi. Kōgyō-Kwagaku-Zasshi (J. Chem. Ind., Tokyo), 1917, 20, 860—872.

THE pasteurisation of saké by the ordinary method often involves exposure to air infection and is attended by a loss of saké of about 2%, owing to the operation being carried out on small quantities

at a time; there is also a loss of alcohol by volatilisation. The authors have designed an electrical heating apparatus which should show a considerable economy and an improved product. The saké is heated for 2½ to 5 hours at 55°–60° C. The consumption of electric power is about 0.06–0.07 kilowatt per litre, showing an average efficiency of 83.4%.—J. F. B.

Methyl alcohol; Detection of — in alcoholic beverages and its formation by the several kinds of yeasts. T. Takahashi, M. Gunke, and T. Yamazaki. J. Amer. Chem. Soc., 1917, 39, 2723–2726.

In the distillates of the beverages examined, namely, wines, whisky, "saké," spirits, and beer, no formaldehyde could be found directly by distillation below 80° C., and after oxidation of the distillates with permanganate and sulphuric acid (this J., 1915, 812), differences were found in the quantities of formaldehyde from methyl alcohol present in the various beverages. The smallest amount of methyl alcohol was found in "saké" except in one sample which contained methyl lactate. In some cases it is necessary to take large samples and concentrate by two or more distillations. All the yeasts tested, "saké", beer-, wine-, and distillery-yeasts, formed methyl alcohol in saccharine fluids (koji extract, raisin extract, Hayduck's solution), the quantity formed being increased by the addition of glycine.—W. G.

Polarimetric determination of starch in grain, milling products, etc. Hals and Heggenhougen. See XIXA.

Comparative examination of pure and commercial inulin. Wolff and Geslin. See XVII.

PATENT.

Beverage; Maltless, non-alcoholic — and process of producing the same. R. Wahl, Chicago, Ill. U.S. Pat. 1,249,259, Dec. 4, 1917. Date of appl., Mar. 9, 1916.

A MASH is made of a material which is devoid of germination diastase, but contains translocation diastase, for instance bran, which is mashed with water and lactic liquor of an acidity of about 2%, containing active lactic acid bacteria. The temperature is maintained favourable to the activity of the bacteria; gelatinised starch is added and the temperature raised to a point favourable to the conversion of the starch. After mashing, the wort is drawn off, boiled with the addition of hops and yeast cells, filtered, and carbonated.—J. F. B.

XIXA.—FOODS.

Milk; Reductase test for —. P. S. Arup. Analyst, 1918, 43, 20–31.

In the modified reductase test as used by Barthel and Orla-Jensen (Milchwirtschaft. Zentralbl., 1912, 14), 40 c.c. of the milk is heated with 1 c.c. of methylene-blue solution, in a covered tube in a water-bath at 38° to 33° C., and the time required for complete decolorisation is noted. As the reducing power of the micro-organisms depends not only on their number, but also on their vitality and capacity for growth (cf. Fred, Analyst, 1913, 38, 62), the author uses a solution containing only 0.015% of methylene blue (1 in 270,000 of milk) so as to reduce the time of action and minimise the possible toxic effect of the dye. From the results obtained in the test in comparison with the

estimation of the number of micro-organisms by Barthel and Orla-Jensen's method of making plate counts, it was found that errors of under-estimation were especially frequent in cold weather. This may be attributed to the reducing power and vitality of organisms which have become predominant at a low temperature being weakened at 38°–39° C.; and this view gains support from the fact that better results are obtained by making the test at 28°–29° C. This lower temperature is also best in the case of pasteurised milk, possibly because it is less favourable to the development of organisms which have survived the pasteurising process. The average optimum temperature of the organisms which survive pasteurisation at a low temperature is higher than that of the organisms in raw milk, whilst in the case of milk which has been heated to higher temperatures the surviving organisms show increased reducing power, probably owing to the elimination of lactic acid bacteria, and the consequent more rapid development of peptonising organisms which grow freely at 38°–39° C. To prevent the results being affected by dissolved oxygen in the milk, it is essential, as suggested by Orla-Jensen, that the samples should be shaken before being placed in the water-bath. By the use of these modifications the efficiency of pasteurisation may be checked, and good, bad, and indifferent samples of milk may be differentiated, but the test is not capable of distinguishing between different grades of milk containing less than half a million organisms per c.c. For distinguishing between "flash-pasteurised" milk (i.e., heated for 30 seconds at the definite temperature), and bulk-pasteurised milk, information would be obtained by the fermentation test at 38°–39° C. In the case of milk which had been heated above 80° C., peptonisation would occur, whereas milk which had been heated at lower temperatures would yield a fine gelatinous curd. A comparison of the times required for reduction at 38° and 28° C. would probably afford information concerning the past treatment of a sample of milk. (See also Ayers and Johnson, this J., 1915, 373.)—C. A. M.

Starch; Polarimetric determination of — in grain, milling products, etc. S. Hals and S. Heggenhougen. Landw. Versuchs-Stat., 1917, 90, 391–414.

EWERS' method (this J., 1916, 432), with slight modification, is recommended for the purpose. The substance is ground to pass a 1 mm. sieve and 2.5 grms. of the powder is placed in a 100 c.c. flask together with 25 c.c. of 1.124% hydrochloric acid. After the mixture has been shaken, the sides of the flask are rinsed down with a further 25 c.c. of the hydrochloric acid, and the flask is placed in a boiling water-bath for exactly 15 mins.; during the first 3 mins. the flask is shaken. Cold water is then added so as to make the volume up to about 90 c.c., the mixture is cooled to room temperature, from 0.25 to 1.5 c.c. of sodium or ammonium molybdate solution (containing 120 grms. of MoO₃ per litre) is added, the whole is diluted to 100 c.c., filtered, and the filtrate polarised in a 200 mm. tube. The reading in angular degrees is multiplied by 10.94, or in Ventzke degrees by 3.79, to obtain the percentage quantity of starch. A correction for water-soluble optically active substances is made by digesting 12.5 grms. of the sample with 250 c.c. of cold water for 1 hour, filtering the mixture, treating 50 c.c. of the filtrate with 2.1 c.c. of hydrochloric acid (sp. gr. 1.125) and heating this mixture in a boiling water-bath for 15 mins. The mixture is then cooled, clarified, and polarised as before, the reading obtained being deducted from that observed in the main determination.

Tomato seeds and skins: Utilisation of waste —.

F. Rabak. Bull. No. 632. Bureau of Plant Ind., U.S. Dept. Agric., Nov. 30, 1917. 15 pages.

In the preparation of tomato pulp the fresh tomatoes are washed by a stream of water under pressure, then cooked with steam, and pulped in a cyclone machine which separates the seeds and skins; or a cold process is used in which, after removal of the "culls," the washed tomatoes pass directly to the cyclone machine. It is estimated that in the U.S.A. about 300,000 tons of tomatoes is annually pulped, and that the moist waste amounts to about 16,000 tons, corresponding to approximately 3300 tons of dry waste, yielding about 1500 tons of dry seeds and 1800 tons of dry skins. This estimate is based upon the data that American tomatoes yield on the average 0.52% of dry seeds and 0.61% of dry skins. In Italy the wet seed and skins are pressed and then dried in a desiccating machine heated by means of steam pipes and containing horizontal conveyors. About 10 tons of the residue is dried in 24 hours, and the seeds are then separated from the skins in a machine containing a series of sieves and fans. The yield of oil from the seeds by extraction with ether or carbon tetrachloride is about 22% of the ground seeds. The extracted oil contains more impurities than the expressed oil, and in the crude state has a slightly rancid odour and a slightly bitter taste, but it can be readily deodorised by the action of steam, and to a large extent decolorised by treatment with fullers' earth and filtration. The refined oil is of a pale yellow colour, and has a pleasant nut-like odour and taste. A sample of extracted refined oil had the following characters:—Sp. gr. at 24° C., 0.9184; refractive index at 25° C., 1.4715; solidification pt., -10° C.; acid value, 2.5; saponification value, 188.6; and iodine value, 114.2. Fatty acids:—Sp. gr. at 25° C., 0.9100; refractive index at 25° C., 1.4655; solidific. pt., 21.5° to 20.5° C.; neutralisation value, 180; iodine value, 104.3; and iodine value of liquid fatty acids, 130. The oil was free from soluble fatty acids, but contained 96.2% of insoluble fatty acids, which were separated by the lead-ether method into 17.54% of solid and 75.81% of liquid fatty acids. The solid fatty acids consisted of about 68% of stearic and 32% of palmitic acid, whilst the liquid fatty acids consisted of about 57% of oleic and 43% of linolic acid. Under the present conditions about 343 tons per annum of tomato seed oil would be available in the United States. Experiments have shown that the oil has a digestibility value of 97, which compares favourably with the value of olive, almond, and cottonseed oils. It would be useful as a culinary and salad oil and would probably yield a satisfactory hydrogenation product for margarine. By cold saponification with caustic soda it yields a soap of good texture with excellent lathering properties. It is a semi-drying oil, yielding a soft sticky film in about 16 days. The residual seed meal had the following composition:—Moisture, 7.15; ash, 4.61; proteins, 37.0; nitrogen-free extract, 29.10; and crude fibre, 22.11%. It thus ranks with cottonseed meal and linseed meal as regards proteins, but the crude fibre is relatively high although lower than that of palm-nut cake. It has been found by Scarpitti that the meal is a valuable feeding-stuff, and has a better effect than linseed cake upon the weight and lactal secretion of cows. The dried skins could be incorporated with the meal, as in Italy, thus increasing the annual available quantity to about 3000 tons.—C. A. M.

Grape syrup ["honey"]. F. Martinotti. Giorn. Vinicolo, 1917, 43, 362. Bull. Agric. Intell., 1917, 8, 1397.

In a process invented by Monti (cp. U.S. Pat.

1,167,006, this J., 1916, 270) grape must is concentrated, first by freezing, which removes the excess of acid, the impurities, and about one-fourth of the water, and then by evaporation under greatly reduced pressure. The product is syrup or "honey" having the nutritive and therapeutic value of grape juice. The must obtained by pressing the grapes, and the liquid obtained from the skins, are mixed either before or after the freezing process.—J. H. I.

"Woody fibre" in feeding stuffs; Determination of —. J. A. and E. W. Voelcker. Analyst, 1918, 43, 31.

In this country the usual method of determining "woody fibre" is that devised by Voelcker, in which the hydrolysis is effected by means of 2% sulphuric acid and 2% caustic alkali solution. In the American and Continental official methods, however, solutions of only 1.25% strength are used, and in the case of oil-cakes from seeds with hard "husks" considerable differences are obtained by the two methods. For example, it is not possible to effect the hydrolysis of palm nut cakes and the like with solutions of lower strength than 2%, and even then vigorous boiling for 30 mins. is required. After extraction of the oil from 3 grms. of the ground sample the residue is boiled for 30 mins. with 125 c.c. of 2% sulphuric acid, the volume of the liquid being kept constant during the boiling. The liquid is then diluted to 400 to 500 c.c. and allowed to settle, the supernatant liquid decanted through a linen filter, and the residue washed on this and returned to the original vessel, where it is boiled for 30 mins. with 2% caustic alkali solution. The liquid is again decanted as before, and the insoluble fibre washed free from alkali, then treated with a little dilute acid, and again washed with water, and finally with alcohol, and dried at 100° C. until constant in weight. Any mineral matter left on ignition is deducted from the weight of fibre.—C. A. M.

Sweet chestnuts; Analytical examination of —. J. L. Baker and H. F. E. Hulton. Analyst, 1918, 43, 32—33.

The average weight of an English chestnut (*Castanea sativa*) was found to be, including the brown skin, 5.45 grms. The skins (17.4% of the nut) contained 49.3% of water, and the kernels (82.6%) contained 59.86% of water. The peeled nuts after being dried and finely ground had the following composition:—Moisture, 4.7; ash, 2.68; ethereal extract (oil), 2.9; proteins, 7.44; reducing sugars (as dextrose), 5.36; sucrose 9.0; starch (Lintner), 50.6; starch (taka-diastase), 41.08; pentosans, 3.06; crude fibre, 2.28; and substances soluble in cold water, 22.08%. The residual material, after removal of substances soluble in water, and starch, contained all the fibre, 65% of the pentosans, 56% of the total proteins, and 90% of the original proteins insoluble in water; when hydrolysed with acid it yielded a reducing sugar (15.7% of the material calculated as xylose) and was almost completely soluble when treated successively with 1.25% acid and 1.25% alkali solution. It was thus probably of the nature of a "hemicellulose." The substances soluble in water contained:—Water, 4.7; ash, 2.1; proteins, 2.8; sucrose, 8.9; dextrose, 5.36; and pentosans, 1.07%. Of the total matter soluble in water 64.6% consisted of fermentable sugars. The aqueous extract of the undried kernel had a diastatic value (Lintner) of less than 0.5.—C. A. M.

Marine algae as fodder for horses; Utilisation of certain —. Adrian. Comptes rend., 1918, 166, 54—56.

CERTAIN seaweeds of the class *Laminaria*, after

washing to remove salts, have a composition which indicates their suitability for fodder. The following is a typical analysis: Moisture, 14.40; carbohydrates, 52.90; proteins, 17.30; cellulose, 11.50; mineral matter, 3.90%. Although poorer in carbohydrates than oats, the seaweed is much richer in protein and, provided it were acceptable and assimilable, this material should serve as a substitute in times of scarcity. In a mixed ration of oats, hay, and straw, the oats were completely replaced by an equal weight of seaweed and fed to twenty cavalry horses for a period of two months. The results were perfectly satisfactory, showing a considerable gain in weight for the animals fed on seaweed as compared with twenty others on the normal ration. It would appear that 0.75 kilo. of the seaweed is equivalent in feeding value to 1 kilo. of oats. The seaweed used is plentiful on the Breton coast.—J. F. B.

Turnip-tops; Losses occurring during ensilage of —. F. Honcamp. Landw. Versuchs-Stat., 1917, 90, 431—442.

WHEN turnip-tops are stored in pits for some months the loss of organic substances amounts to about 30%; the greatest loss is in the carbohydrates, but the proteins are also diminished to a considerable extent. Storage after artificial drying is to be preferred, but cheaper and more efficient apparatus than that at present available would be required.—W. P. S.

PATENTS.

Meal or flour and milling products; Process for treating —. Naamlooze Vennootschap Industriele Maatschappij voorheen Noury and Vander Lande, Deventer, Holland. Eng. Pat. 102,967, Dec. 21, 1916. (Appl. No. 18,325 of 1916.)
• Under Int. Conv., Dec. 22, 1915.

FLOUR is mixed with 0.7% of a 3% solution of hydrogen peroxide and is transported by a belt conveyor through a room containing mercury vapour lamps of 200 volts each. The layer of flour on the belt is 3 cm. deep, and 200 kilos. of flour is treated by each lamp per hour. Decomposition of the peroxide may be brought about also by passing the flour down a shoot between electrodes, and by stirring the flour in a drum by means of zinc plates. Instead of hydrogen peroxide any inorganic or organic peroxide or both may be used, either in solution, suspension, or the solid state. The treatment is claimed to improve both the colour and the baking qualities of the flour.—J. H. J.

Bread making; Art of —. R. and A. S. Wahl. Chicago. U.S. Pat. 1,217,319, Nov. 20, 1917. Date of appl., Sept. 12, 1916.

A MASH containing phosphates, proteins, and the peptonising enzyme of malt is digested at 45° C., and then added to the dough. A mash containing the aleurone layer of seeds and lactic acid is maintained under conditions favouring the proteolytic digestion of the proteins, starch is then added and, when this has been hydrolysed by the diastase in the seeds, the mixture is added to the dough. Yeast is added to a solution of yeast food or "bread improver" having a cereal base, and, when the solution has become charged with carbon dioxide, the mixture is incorporated with the dough.—W. P. S.

Milk and other liquids; Process and apparatus for condensing and reducing to powder —. E. C. R. Marks, London. From Merrell-Soule Co., Syracuse, N.Y., U.S.A. Eng. Pat. 111,508, Nov. 24, 1916. (Appl. No. 16,858 of 1916.) (See also U.S. Pat. 1,225,348 of 1917; this J., 1917, 633.)

MILK is passed into the bottom of a heated centrifugal chamber and is made to pass spirally up the side of the chamber by the rotation of a beater at a high speed, and in so doing is concentrated by evaporation. The concentrated portion passes out at the top. The vapour given off passes into a condensing chamber and its rapid condensation causes a vacuum of 23—26 inches of mercury in the centrifugal chamber. As the concentrated milk passes out of the centrifugal chamber it may be atomised into a forced current of heated air and reduced to powder form.—J. H. J.

Milk-serum powder and process of making same. A. W. Bosworth, Milton, Mass., Assignor to The Boston Floating Hospital, Boston, Mass. U.S. Pat. 1,246,858, Nov. 20, 1917. Date of appl., Aug. 9, 1917.

FAT, casein, and all but a trace of calcium and other inorganic phosphates are removed from milk in such a way that the vitamins are not destroyed, and the liquid is then evaporated to dryness at a low temperature.—W. P. S.

Butter substitute. R. H. Adams, Ridgewood, N.J., and H. Beatty, Hinsdale, Ill. U.S. Pat. (A) 1,247,482 and (B) 1,247,483, Nov. 20, 1917. Date of appl., Feb. 10, 1917.

(A) THE water-insoluble solids of ripened milk are mixed with a large quantity of solid coconut oil. (B) Varying quantities of solid coconut oil and the water-insoluble solids of butter-milk are mixed together, e.g., 3 parts of coconut oil to 1 part of butter-milk solids.—W. P. S.

Rice food product. A. Matsuo, San Francisco, Cal. U.S. Pat. 1,248,884, Dec. 4, 1917. Date of appl., Apr. 18, 1917.

COOKED rice is fermented with barley malt, the liquid is removed by straining, and the solids are macerated with more cooked rice and then dried in thin flakes. The method may be varied by adding Japanese saké and glucose before macerating.—J. H. J.

Flesh; Method of preserving —. G. D. Rogers, Gloucester, Mass. U.S. Pat. 1,249,205, Dec. 4, 1917. Date of appl., Sep. 1, 1917.

FLESH is packed in sodium chloride and a solution of sodium hypochlorite.—J. H. J.

Carbonic acid solution; Stable — and method of producing same. E. Rudolfi, Assignor to L. E. Elkan Erben Ges. m. b. H., Berlin-Westend, Germany. U.S. Pat. 1,247,334, Nov. 20, 1917. Date of appl., June 25, 1914.

CARBONATED waters containing a relatively large quantity of carbonic acid are prepared by dissolving carbon dioxide in an aqueous liquid containing chlorophyll or a chlorophyll derivative.—W. P. S.

XIXB.—WATER PURIFICATION; SANITATION.

[Sewage] sludge; Nature of activated —. F. Diéniert. Comptes rend., 1917, 165, 1116—1117.

To prepare activated sludge from Paris sewage, it was found necessary to aerate the sewage for 30 hrs. to effect the nitrification of the 10 mgrms. of ammonia per litre which it contained. The liquid was then decanted, a further volume of

sewage was admitted to the residual sludge, and aeration was continued. These operations were repeated for 15–20 days, when the time required for nitrification had been reduced to one and a half hours and the volume of sludge had much increased. The sludge was then in an activated condition. During the aeration the dissolved carbon dioxide is expelled and the calcium bicarbonate is precipitated as carbonate; at the same time the precipitate removes some of the suspended and dissolved organic matter by adsorption. It was found that the alkalinity of the sewage was reduced from 180 parts to 60 parts of lime per million by one and a half hours' aeration. The activated sludge contained 50% of mineral matter, chiefly calcium carbonate, 20% of albuminoid matter, and 30% of non-albuminoid matter. In tests in which the sewage took about 2 hours to travel along the sewers, it was found that in consequence of the aeration which took place during that time, about three-fourths of the albuminoid and ammoniacal matter was adsorbed by the precipitated calcium carbonate and was found in the deposits of calcium carbonate along the sewers.—J. H. J.

Dichloramine T and chlorinated eucalyptol (sp. gr. 1.2). R. B. Krauss and E. Crede. J. Amer. Chem. Soc., 1917, 39, 2720–2722.

For the preparation of dichloramine T on a large scale, toluene-*p*-sulphonamide is dissolved in ten parts of 1:10 sodium hydroxide (39° B., sp. gr. 1.345) and diluted with twenty parts of water. The solution is filtered and chlorine is passed in until a voluminous white precipitate is formed, which is collected, washed with 5–8 parts of water and finally and quickly with enough 10% alcohol to make a thin paste. The substance is separated on a vacuum filter and dried at below 55° C. in a vacuum drier. The product has a negligible ash, and good chlorine content, but does not evolve free chlorine on standing. The following specifications are given as most suitable for the material when used for surgical purposes:—White powder or crystals, m.p. 78°–84° C., soluble in cold chloroform with slight to no turbidity, and soluble in prepared eucalyptol (Dakin) or chlorinated eucalyptol (sp. gr. 1.2). When chlorine is passed into eucalyptol exposed to good daylight, the rate of passage of the gas being controlled so that the temperature does not rise above 89° C., a chlorinated eucalyptol (sp. gr. 1.2) is obtained, which after washing with water, shaking with anhydrous sodium carbonate, and drying over fused calcium chloride, is left as a slightly amber-coloured oil, chlorine content 31%, which will dissolve 20% of dichloramine T and may be used at full strength on the skin or an open wound, without the need for dilution with prepared paraffin oil.—W. G.

Cresol: Preparation of a preservative from—. M. Nevin and B. Mann. J. Amer. Chem. Soc., 1917, 39, 2752–2756.

If commercial cresol is fractionally distilled, the process being repeated three times, a fraction is obtained, having b. pt. 199°–204° C., sp. gr. at 25° C. 1.030, which has a toxicity equal to that of phenol, and only slightly lower than that of Schering's "Trikresol," and a phenol (germicidal) coefficient of 2.55, which is higher than that of "Trikresol."—W. G.

Guaiacol and benzoic acid; Physiological properties and medico-surgical applications of—. L. Men-ière. Comptes rend., 1917, 165, 1023–1025.

AN antiseptic solution, containing guaiacol and benzoic acid, with or without other aromatic substances, such as eucalyptol, has been extensively applied in France in the treatment of

wounds, and with great success. It has powerful antiseptic properties, but is not toxic towards cellular protoplasm, and unlike hypochlorite it has no solvent action on animal tissue. Pieces of flesh immersed for 15 months in an aqueous solution containing 5 grms. of guaiacol, 4 grms. of alcohol, and 1 grm. of benzoic acid per litre, underwent no apparent change, and when afterwards left in the air they remained immune from putrefaction. Intravenous injection of much stronger solutions had no injurious effect on rabbits.—J. H. L.

PATENTS.

Sewage; Tanks for the purification of—. G. W. and J. F. Naylor, Denby Dale, Yorks. Eng. Pat. 111,548, Dec. 7, 1916. (Appl. No. 17,569 of 1916.)

THE air-diffusing means along the bottom of a tank for the treatment of sewage by diffusion of air in small bubbles, may consist of non-porous tubes with small perforations on their under sides, covered by strips of cloth, tightly encircling the tube. The whole length of the tube is enclosed by a cloth casing kept from touching the under side of the tube by depending stays. The air from the perforations in the tube diffuses through the cloth casing, mainly through the sides. The tubes may be made also of porous earthenware, the upper surface being painted over so that air escapes from the sides only.—J. H. J.

Sewage and other impure liquids; Purification of—. W. Jones, Stourbridge, Worcestershire, and Jones and Attwood, Ltd., Amblescote, Staffordshire. Eng. Pat. 111,720, Dec. 9, 1916. (Appl. No. 17,718 of 1916.)

CRUDE sewage enters a treatment tank through a hydropneumatic appliance whereby a mixture of sewage and air is delivered well below the surface into the body of the liquid in the tank. The bottom of the tank is of inverted conical shape with a sump at the apex, and the dilute sludge passes out by the sump into a separate tank with ridged bottom provided with air diffusers, whereby it is aerated and circulated. This invigorated sludge is then returned by an air-lift to the top of the liquid in the sewage tank. In another form of the tank, the mixture of sewage and air is delivered into radial arms at the level of the conical portion of the tank, and as it issues from these through a series of holes along one side, it causes them to revolve and bring about a perfect distribution. The process may be carried out also in several tanks connected in series.—J. H. J.

Filtration [of water]; Art of—. W. M. Jewell, Assignor to Jewell Engineering Co., Chicago, Ill. U.S. Pat. 1,248,127, Nov. 27, 1917. Date of appl., May 12, 1913.

THE process is a combined method of water filtration and filter cleansing, in which, when the filter requires to be cleaned, the flow of the filtered water is reversed through the same path in which it is discharged from the filter.—J. H. J.

Waters; Method for treating ferruginous—. L. S. Hughes, Chicago, Ill. U.S. Pat. 1,248,329, Nov. 27, 1917. Date of appl., Oct. 2, 1913.

MINE water is treated by passing over small pieces of broken limestone, and then over relatively larger pieces at a higher velocity.—J. H. J.

XX.—ORGANIC PRODUCTS; MEDICINAL SUBSTANCES; ESSENTIAL OILS.

Chemical constitution and physiological action; The relation between—. F. L. Pyman. Chem. Soc. Trans., 1917, 111, 1103–1128.

THE study of the relation between chemical

structure and physiological action is complicated by the almost total absence of general laws, and a substituent group may have a pronounced influence in one case but none at all in a parallel case. Even with such simple nerve reactions as smell and taste, the relations between members of homologous series are not always constant, and stereoisomerism, whether due to asymmetry of C or N atoms, may sometimes have no influence, while in many cases it is associated with a partial or complete reversal of physiological character. Variations in the physiological activity of stereoisomerides may possibly be due to the formation of additive compounds with the organic tissues in the case of one and not the other of the isomerides. Other differences may be traced to simple differences in physical and chemical properties, e.g. solubility, which may influence the distribution of the substance in the animal organism, or the liberation of bases from their salts by the alkalinity of the blood. Instances of profound physiological modification, resulting in total inactivity, are often found by the introduction or liberation of sulphonic or carboxylic acid groups in the molecule of an active base, which may also perhaps be attributed to reaction with the blood alkalinity. Similarly the formation of quaternary salts from alkaloids may very largely neutralise their activity, which returns when the tertiary character is restored, e.g., by hydrogenation. Certain alkaloids are almost identical in physiological action yet have little in common as regards chemical structure, for instance, the group nicotine, lobelline, and cystine or the group muscarine, arecoline, and pilocarpine. For systematic investigation it is necessary to select a particular drug the physiological action of which is capable of quantitative measurement, and to study comparatively the effect of a large series of substituent variations in different groups of its molecule. A convenient series for such a study is that of the tropeines, typified by atropine, the *dl*-tropic ester of tropine, which is characterised by its mydriatic activity. Atropine is the racemic form of hyoscyamine, the pure *l*-hyoscyamine being about 100 times as active as the *d*-constituent. No tropeine of an aliphatic acid has been found to possess mydriatic activity in dilute solution, but the closed ring of the acyl residue need not be of the benzene type, since active tropeines of pyridyl acids exist. It is not essential that a mydriatic tropeine must contain an alcoholic hydroxyl in the side chain carrying the carboxylic group, nevertheless those tropeines possessing a high mydriatic power do contain such hydroxyl. The acid sulphuric ester of this hydroxyl is in all cases inactive; tropeines containing an unsaturated linkage in the carboxylic side chain are also inactive. The local anaesthetic effect characteristic of the alkaloid cocaine has been proved to be associated with the chemical type of esters of amino-alcohols. The acyl group in the majority of cases of practical utility is aromatic, generally benzoyl, but a ring complex does not appear to be essential. Substitution in the benzoyl residue lowers the activity; cinnamoyl-cocaine is inactive. In other cases, e.g., alypine and novocaine, the substitution of the cinnamoyl group for the benzoyl increases the activity. The amino group may be secondary or tertiary or may be associated with simple or bridged rings. Cocaine, tropacocaine, eucaine, alypine, and novocaine all represent different types of nitrogen linking. Norcocaine, in which the NCH_3 becomes NH , is more active than cocaine but the primary amine corresponding to novocaine is inactive. The alcohol group may be primary, secondary, or tertiary and may separate the acyl and amino groups by a chain of two or three carbon atoms. Adrenaline, which is β -3,4-trihydroxy- β -phenylethylmethylamine, has a vasoconstrictor action which can be measured by the rise of blood pressure.

Although catechol causes a rise of blood pressure, the action of adrenaline is not due to the catechol residue contained therein, since the type of physiological action is entirely different. A large number of amines possess the characteristic property in a more or less slight degree, but the only compound with an activity comparable with that of adrenaline is the primary ethylamine of corresponding constitution; *l*-adrenaline is considerably more active than the racemic form. Protozoacidal drugs are typified by the alkaloids quinine and emetine, and experiments have been made to find derivatives of related constitution which would be more deadly to infusoria (protozoa) and less toxic to mammals. The results obtained *in vitro*, however, have not been borne out in clinical practice. Ethylhydrocupreine hydrochloride appeared in the laboratory to offer the advantages over quinine sulphate which were desired, but in practice it was inferior; hydroquinine hydrochloride was the most valuable. In the emetine series the full amoebicidal action is not obtained unless the emetine nucleus is intact; none of the related alkaloids was superior to emetine in practice. In fact, in none of the cases discussed above are the natural products, hyoscyamine, cocaine, adrenaline, quinine, and emetine, surpassed in point of maximum effect by any of their derivatives, nevertheless useful additions to medicine have resulted from the researches.—J. F. B.

[*Essential*] oil of *Artemisia annua*. Asahina and Yoshitomi. J. Pharm. Soc. Japan, 1917, No. 424, 1. Perf. and Essent. Oil Rec., 1917, 8, 353—354.

THE work of Imada on the essential oil of *Artemisia annua* has been extended. The oil used had the following characteristics:—Sp. gr. at $16^{\circ}/4^{\circ}C.$, 0.90798; optical rotation, $16-19^{\circ}$; acid value, 1.82; ester value, 34.58; ester value after acetylation, 63.54. A minute quantity of an oil with an odour of cinnic aldehyde was extracted by sodium bisulphite solution. The remainder was steam-distilled, yielding an oil of low specific gravity. The brown residue, amounting to about one-fifth of the original oil, distilled between 128° and $182^{\circ}C.$ at 10 mm. pressure. The fraction of the light oil distilling from 176° to $181^{\circ}C.$ contained cineol. The fraction distilling from 181° to $190^{\circ}C.$ contained a ketone yielding a semicarbazone melting at $96^{\circ}C.$, from which concentrated hydrochloric acid regenerated the pure ketone, having the formula $C_{10}H_{16}O$, boiling at $71^{\circ}-75^{\circ}C.$ at 11 mm., and at 182° at 760 mm. Its sp. gr. at $14^{\circ}/4^{\circ}C.$ was 0.8906, refractive index 1.4695 at $18.5^{\circ}C.$, and it was optically inactive. Catalytic reduction by hydrogen in the presence of platinum black yielded a tetrahydroketone, forming a semicarbazone melting at $134^{\circ}-135^{\circ}C.$ The pure tetrahydroartemisia-ketone boiled at $73^{\circ}C.$ at 15 mm., and at $173^{\circ}C.$ at 760 mm.; sp. gr. at $19.5^{\circ}/4^{\circ}C.$, 0.8262, and refractive index 1.42425. The higher-boiling fractions of the oil ($190^{\circ}-210^{\circ}C.$) yielded a semicarbazone melting at $236^{\circ}-237^{\circ}C.$, which when treated with dilute sulphuric acid yielded a solid ketone, m. pt. $175^{\circ}C.$, with all the properties of *l*-camphor.—F. SP.

[*Essential*] oils of *Darwinia*. H. G. Baker and R. T. Smith. J. Proc. Roy. Soc. N.S.W., 1918, 1. Perf. and Essent. Oil Rec., 1917, 8, 355.

THE following are the characteristics of the essential oils of three species of *Darwinia*. (1) *D. fascicularis*. Sp. gr. 0.9184; optical rotation $+1.2^{\circ}$; esters (hot saponification) 60%; esters (cold saponification) 58%; yield, 0.318%. (2) *D. grandiflora*. Sp. gr. 0.915; optical rotation $+23.1^{\circ}$; refractive index, 1.4773; esters (hot

saponification) 35.1% : esters (cold saponification) 33.8% : yield, 0.12%. (3) *D. laxifolia*. Sp. gr. 0.8779 : optical rotation, -6.5° : esters (hot saponification), 5.3% : yield 0.313%. The oil from *D. grandiflora* is red and somewhat mobile. The difference of 3.7 between the hot and cold saponification values is said to be due to the presence of geranyl butyrate, the main ester being geranyl acetate. The mixture of barium salts from the liberated mixed acids contained 92.15% of barium acetate and 7.85% of barium butyrate. A considerable portion of the oil distilled between 156° and 160° C., and about 30% below 165° C. This fraction had a terpene-like odour, sp. gr. 0.872, optical rotation 41.6° , and refractive index 1.4685. Its nitrosochloride melted at 104° C. It is therefore *d*-pinene. The pinene in the oil from *D. laxifolia* is levorotatory, and in the oil from *D. fascicularis* dextro-rotatory.—F. Sp.

Lemon grass oil: Constituents of Formosan —. H. K. Kafuku. Kōgyō-Kwazaku-Zasshi (J. Chem. Ind., Tokyo), 1917, 20, S25—S33.

THE terpene isolated from lemongrass oil from Formosa (this J., 1916, S65) gave, on reduction with sodium and alcohol, a derivative corresponding closely with dihydromyrcene, yielding dihydromyrcene tetrabromide, m. pt. 87° — 88° C. It was further reduced by hydrogen and platinum to 2,6-dimethyloctane. On oxidation with alkaline permanganate it yielded succinic and oxalic acids. The identification of this terpene with myrcene is considered complete. In addition, the oil contains an aldehydic substance, other than citral, which has not yet been isolated.—J. F. B.

Tannic acid, gallic acid, and pyrogallol: Preparation of —. M. Mito. Kōgyō-Kwazaku-Zasshi (J. Chem. Ind., Tokyo), 1917, 20, 720—736.

TANNIN was extracted from Japanese gall nuts by four successive treatments with water at 20° to 30° C., and the residue was pressed. In this way a 13% solution of tannin containing 82% of the theoretical quantity was obtained. Tannic acid was prepared by concentrating the extract to 20%, extracting it with half its volume of ether, and evaporating the ethereal extract. About 75% of the tannin in the aqueous extract was obtained. For the preparation of gallic acid the residual solution from the tannic acid preparation was concentrated to 20%, and treated with 15 to 20% (by vol.) of sulphuric acid (66° B., sp. gr. 1.84), and the precipitated black mass was dissolved in water, decolorised with animal charcoal, and finally recrystallised from water. The yield was 62% of the tannin contained in the residual solution. Pyrogallol was prepared by heating the crude gallic acid with about 3 times its volume of water in an autoclave at 210° C. The crude product (yield, 63.5% of the gallic acid) was purified by crystallisation from pure benzene.—C. A. M.

Nitriles: Catalytic method for the preparation of aromatic —. A. Mailhe. Comptes rend., 1918, 166, 36—38.

THE vapour of an alkyl ester of an aromatic acid, mixed with gaseous ammonia, is passed through a tube containing thoria heated to 450° — 470° C., and the nitrile is purified by fractional distillation of the oily layer of the liquid obtained. Good yields of nitriles have been obtained from the alkyl esters of benzoic, toluic, and phenylacetic acids. (See also J. Chem. Soc., Feb., 1918).—J. F. B.

Corrosion of metals: Hydrolysis of organic halides and the —. [Colour reaction of tetrachloroethylene.] H. W. Doughty. J. Amer. Chem. Soc., 1917, 39, 2685—2692.

THE corrosion of metal containers (tin cans) by moist carbon tetrachloride cannot be due merely

to the hydrolysis of the organic halide and subsequent action of the hydrochloric acid upon the metal, since in the case of iron and copper the corrosion is very greatly increased by the presence of ammonia. The hydrolysis of carbon tetrachloride is greatly accelerated by iron and copper. It is also accelerated by hydrogen ions and hydroxyl ions, especially at elevated temperatures. A number of organic halides were examined as to their action on copper in the presence of water and ammonia, and the corrosion was found to be most pronounced with compounds containing a trichloromethyl group, monohalogen derivatives having practically no action.

A colour test for tetrachloroethylene is given. When this compound is allowed to stand in contact with water, ammonia, and copper, the aqueous layer develops a rich, red colour.—W. G.

Test for tartrates depending upon the formation of the copper-tartrate complex. Curtman and others. See VII.

PATENTS.

Acetaldehyde: Method of preparing —. H. Hibbert. Pittsburgh, Pa., Assignor to Union Carbide Co., New York. U.S. Pat. 1,247,270, Nov. 20, 1917. Date of appl., Apr. 28, 1916.

ACETYLENE is combined with the elements of water in an acid bath containing a mercury compound, maintained at a suitable temperature for the continuous distillation of acetaldehyde, and the mixture of acetaldehyde and acetylene is conveyed to one or more baths connected in series with, and similar in composition to, the first bath.—F. W. A.

Vaccin for the prevention of hog-cholera and product therefrom; Manufacturing —. M. J. Couret, Assignor to Louisiana Biological Products, Incorp., New Orleans, La. U.S. Pat. 1,246,059, Nov. 13, 1917. Date of appl., Feb. 16, 1917.

A VACCIN product for the prevention of hog-cholera is produced by removing from the hog those parts containing the virulent virus, removing solid particles, extracting the liquid residue with chloroform, separating the chloroform at a temperature not above 45° C., and desiccating the residue at about 10° C. The yield is increased by injecting into the animal a liquid germ culture containing dextrose, having an acid reaction and possessing exosmotic properties.—L. A. C.
